INDEX TO VOLUME I., 1931.

REFERENCES AND ABBREVIATIONS

Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings. Institutions and Corporations with the right to the prefix Royal will be found under that prefix, with the exception of Hospitals, which will be found under that heading; and Medical Societies, which are separately indexed under Societies. All Universities are indexed under the word University. (A.) = Annotation, (C.) = Correspondence, (N.I.) = New Inventions, (L.A.) = Leading Article, (M.L.) = Medico-legal, (M.T.T.) = Modern Technique in Treatment, (O.) = Obituary, (P.I.) = Parliamentary Intelligence, (R.) = Review, (R. and A.) = Reports and Analyses, (A.D.) = Clinical Interpretation of Aids to Diagnosis, (N.P.) = New Preparations, and P. and C.P. = Panel and Contract Practice.

Concordance of page numbers and dates of issue will be found at the end of the Index.

A

bdomen—pain in lower, 412
bdomino-pelvic Diagnosis in Women (A. J. Walscheid) (R.), 1034
bel, A. L., cancer of rectum, 1240; treatment before and after operation, 1191; (A.), 1251
erdeen—Infirmary, 238; University Club, London, 1060
ernethy, John, fresh light on (A.), 930
ortion—criminal, and professional secrecy (M.L.), 882; criminal, in London, 1365; induction of (M. Salmond), 745; legality of, in Germany, 492; *prosecution for, in Germany*, 1257
rahams, A., Exercise, its Functions, Varieties, and Applications (R.), 356
cident—removal of patient from road after (M.L.,) 375, 1102; prevention, *calendar of*, 392; prevention, organisation of (A.), 535
cident neuroses, psychology of (L.A.), 87
commodation, spasm of (A.), 1410
hlorhydria, clinical conditions associated with (*J. F. Wilkinson and T. H.* Oliver), 66; (L.A.), 86; (A. F. Hurst) (C.), 163; (T. H. Oliver) (C.), 217
land, T. D. (O.), 942
riflavine—and hepatitis (E. R. Cullinan) (C.), 228, 498, (C. A. Birch) (C.), 269, (H. M. Hanschell) (C.), 269, (T. Y. Simpson) (C.), 323; in uterine infection (A.), 143, (G. H. Morrison) (C.), 217
tinomycotic cerebro-spinal meningitis (L. W. Cann and G. J. Hollis), 130
ctinotherapy—at tuberculosis dispensary (G. Jessel), 1182; *see also* Radiotherapy and Ultra-violet ray
dair, F. E., Cancer (R.), 1402
dams, J. A. (O.), 164
dams, S. H., Modern Sewage Disposal *and Hygienics (R.), 356*
ddison, W. H. F., Piersol's Normal Histology (R.), 192
ddison's disease, treatment of (A.), 652
denoids and rickets (L.A.), 301
dhesive outfit, 1436
dler, A., individual psychology, 225; structure of neurosis, 136
dvertisements in German medical journals, 492
fter-care, mental (A.), 91
granulocytic angina (L. P. Garrod and *R. H. Williams*), 469
guiler, J. E., aphthous ulcers (C.), 1161
ir routes and yellow fever, 315
lbrecht, H. U., Das Ulcusproblem im Lichte moderner Röntgenforschung (R.), 761
Albuminuria following blood extravasation, 1033
Alcohol—and heredity, 317; and the motorist, 223
Alcoholism (Sir T. Horder), 1193
Alepol, sulphur, and turpentine injections *in persistent psychosis (D. Macmillan* and A. McN. Wyllie), 909
Alexander, H. L., Bronchial Asthma, its Diagnosis and Treatment (R.), 1034
Alexandra Rose Day, 1431
Allen, A. H. B., Pleasure and Instinct (R.), 646
Allen, C. E., motives and mechanisms of the mind (C.), 270
Allen, F. M. B., Diseases of Infants and Children (R.), 83
Allen, H., adequate treatment of syphilis *(C.), 1265*
Allison, R. S., and Davies, R. Picton, treatment of functional anorexia, 902
Almoner's department (A.), 1253
Almquist, E., Grosse Biologen (R.), 1196
Alstead, S., and Chamberlain, E. N., unusual *complications of diphtheria*, 970
Aluminium in cooking, 47; (A.), 35
Ambulance involved in motor accident (M.L.), 375, 1102
Amenorrhœa, ovarian extract in (H. Gardiner-Hill and J. Forest Smith), 464
Among the *Thinkers: Leaves from My* Note-books (J. A. Lindsay) (R.), 815
Amytal—in childbirth (I. W. Magill), 74, (A.), 92, (J. Riddell) (C.), 162, 498, (A.), 1410; in diseased heart, 623
Anæmia—aplastic (W. J. Fenton and A. Turner), *1188, (A. F. Hurst) (C.)*, 1267; iron in (A.), 483; liver in (J. Vaughan), 702
Anæmia, pernicious—amino-acids in (A.), 255; blood-platelets in (S. C. Dyke and W. Stewart), 1080; diagnosis of *(S. C. Dyke), 703; intravenous injection* of liver in (W. B. Castle and F. H. L. Taylor), 857; mental changes in (A.), 1359; stomach extracts in (J. F. Wilkinson), 703; virus in (A.), 306
Anæsthesia—(W. S. Syke) (R.), 1141; *burns during* (M.L.), 265, (A.), 305, (C. Gibson) (C.), 378, (Sir F. Shipway) (C.), 378; Gwathmey, in labour, 643, (A.), 1202; in childbirth, 495, (S. Churchill) (C.), 554, 588, 643; inhalation, technique of, 759; in mental *cases, 60; vomiting after* (B. E. Cook), 860; (C.), 1159; (A. H. Macklin) (C.), 1054; *see also* Amytal, Analgesia, Avertin, Barbiturates, Ether, Nembutal, Nitrous Oxide, Pernocton
Anæsthetics—accessories to, 586, (L.A.), 595; (I. W. Magill) (C.), 670; "aeris," new name for nitrous oxide (B. Gardner) (C.), 1161; choice of (I. W. Magill), 353; explosion of (A.), 1149; Handbook of Practical Anæsthetics (C. F. Hadfield) (R.), 815
Anal fissure, treatment of (C. Howard), 914
Analgesia—pantocaine in, 727; percaine in, 213; (A.), 422; spinal (A.), 360, 1043; duracaine in (W. H. Jones) (C.), 936, 1160; (E. F. Hill) (C.), 1101
Anaphylaxis—Le choc anaphylactique et le principe de la désensibilisation (A. Besredka) (R.), 644; Les phénomènes de choc dans l'urticaire (P. Vallery-Radot and L. Rouques) (R.), 645
Anatomical specimens, preservation of (A.), 653
Anatomical Stepping Stones to Surgery (L. B. Rawling) (R.), 814
Anatomist and Other Plays (J. Bridie) (R.), 1141
Anatomy—Anatomy in the Living Model (D. Waterston) (R.), 705; Handbook of Anatomy (J. K. Young) (R.), 921; Developmental Anatomy (L. B. Arey) (R.), 869; Text-book of Anatomy and Physiology (E. R. Bundy) (R.), 1152; *Warren's Handbook of Anatomy (R.)*, 869
Anderson, Sir A., sweepstakes and hospitals (C.), 1052
Anderson, J. *(O.), 832*
Anderson, T., serum treatment of pneu*monia (C.), 162*
Andrewes, C. H., immunity in virus diseases, 989, 1046
Aneurysm—case of (J. L. Swanston), 810; dissecting, of aorta (E. A. Wood), 402; popliteal, 920; unequal pulse in, 920
Anginal pain—ischæmia and, 1138, (Sir T. Lewis) (C.), 1322; palliation of (A.), 1308
Angina pectoris—and myocardial pain (A.), 874; electrocardiographic changes *in (J. Parkinson and D. E. Bedford)*, 15
Angiohypotony, constitutional (A. Ferrannini), 1131
Animal—Animal Mind (C. L. Morgan) (R.), 476; Animal year book, 1220
Animals—laboratory, diseases of (Anatomie und Pathologie der Spontanerkrankungen der kleinen Laboratoriumstiere) (R. Jaffé) (R.), 921; living, experiments on (A.), 92, (P.I.), 1166, 1214, 1430; poison gas experiments on (P.I.), 616; radiography in, 23 *surgery in (A.)*, 1098
Anorexia—functional, treatment of (R. S. Allison and R. Picton Davies), 902; (R. D. Gillespie) (C.), 995; nervosa, 865
Antarctic, Mawson Expedition to, 48
Antenatal Care (W. F. T. Haultain and E. C. Fahmy) (R.), 645
Anthracosis, silicosis, and tuberculosis in coal-miners (S. L. Cummins), 235
Anthrax, fatal case of (A. L. K. Rankin), 407
Antivirus after mastoid operations, 113

Aphthous ulcers (F. A. Phillips) (C.), 777; (J. E. Aiguier) (C.), 1161
Apical infection of teeth (L.A.), 1144
Appendicitis—causation of (Der Appendicitische Anfall) (L. Aschoff) (R.), 815; heart-block following (L. B. Cole), 907; in the schoolboy (C. L. Leipoldt) (C.), 51
Appendix, mucocele of (J. B. G. Muir), 131
Appetite, loss of, *see* Anorexia
Appointments, weekly lists of, 54, 108, 168, 222, 279, 334, 390, 448, 564, 621, 680, 735, 788, 840, 891, 946, 1005, 1061, 1114, 1167, 1219, 1271, 1328, 1380, 1432
Aqueous humour, drainage of (A.), 1360
Archdall, M., ramisection in spastic weakness (C.), 552
Arey, L. B., Developmental Anatomy (R.), 869
Arginase in blood in cancer (A. Haddow), 1021
Argyll Robertson pupil, non-luetic, 973
Armour, D., treatment of head injuries, 1193
Armstrong, J. R., novasurol and heart failure in Graves's disease, 808
Army, health of, in 1929, 376
Arosa, tuberculosis in population of (L.A.), 764
Arthritis—L'arthritisme: ses misères, ses dangers, son traitement (J. Sedillot) (R.), 1141; gonococcal (D. Lees), 640; gonococcal, in new-born child (A. D. C. Bell and P. A. Clements), 1349; rheumatoid, treatment of (A. H. Douthwaite), 785, (C.), 886, (C. E. Jenkins) (C.), 835; suppurative, due to hæmophilic bacillus (H. E. Mansell), 471
Artificial pneumothorax — apparatus (A. C. M. Elman and H. Cameron-Wright) (N.I.), 1244; (V. S. Hodson and R. S. Johnson), 1028; future of, 811; in abscess of lung, 1319; La collapsothérapie de la tuberculose pulmonaire (M. Leon-Kindberg) (R.), 1245
Artificial respiration—prolonged administration of (A.), 1150; (P. Drinker), 1886; (W. Smith) (C.), 1267
Artificial sunlight, 1220
Artists, medical men as, 1157
Arvedson, J., Swedish Medical Gymnastics and Massage (R.), 1302

UTERINE HÆMORRHAGE, WITH SPECIAL REFERENCE TO MALIGNANT DISEASE.*

By Beckwith Whitehouse, M.S. Lond., F.R.C.S. Eng.,
PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY OF BIRMINGHAM.

During the year 1929, 4428 women died in England and Wales alone from malignant disease of the uterus. This is the average toll as shown by statistics covering the last quinquennium, the death-rate from this cause amounting to 215 to 220 per million women.

Cancer of Uterus: England and Wales.

Mortality 1925–29.

Year.	Number of deaths.	Rate per million females.
1925	4467	220
1926	4409	217
1927	4428	216
1928	4525	220
1929	4428	215

In the female sex two organs of the body have a greater predisposition to cancer than others. These are the uterus and the breast, and in each the liability is about the same. Indeed, we may even go further and say that in 30 per cent. of all women who suffer from cancer the organ first involved is the uterus.

The earliest, and for that reason the most important symptom of carcinoma affecting the uterus, whether it be cervix or corpus, is almost invariably hæmorrhage. Some years ago Wilson in a series of 328 cases found that uterine bleeding *alone* was the first symptom in 41 per cent. If discharge and pain are included, this figure is materially increased, and hæmorrhage may be regarded as *one* of the earliest symptoms in 65 per cent. of the whole.

As regards curability, uterine cancer occupies a very unfavourable position as contrasted with cancer of the breast. The reason for this is not far to seek; it is that cases reach our hands too late, and by the time that the disease is subjected to treatment, whatever form that may take, it has already generally extended beyond the aid of such therapeutic measures as are available to-day. In 1929, 53 new cases of carcinoma of the cervix passed through my clinic, but of these only three were in a clinical state which might reasonably be expected to be followed by cure. The rest were advanced growths; three-quarters of these women had attributed the hæmorrhage to the menopause, and no local examination of the tissues had been made. I do not believe that this state of affairs is by any means isolated. It still probably obtains throughout the world.

We hear at times a certain amount of adverse criticism of cancer propaganda work and of the development of a state of cancerophobia in the middle-aged matron of to-day. Personally I regard this as a healthy sign and a mark of progress. Without a certain amount of fear we shall not get women, especially of the uneducated classes, to submit themselves to the careful and detailed investigation necessary to ensure a correct diagnosis. We must not forget that to the average woman, uterine hæmorrhage is the least sign of importance to her. She is so accustomed to slight irregularities in the menstrual function, especially at the menopause—and probably she knows many of her friends with similar symptoms who have not died from cancer—that a very strong stimulus is necessary to make her seek advice. The only stimulus that we possess *is* cancerophobia, and for that reason I do not deprecate, I welcome it! Anyone, I am sure, would rather examine 100 women and cure their "phobias" by proving there is no malignant disease present, than be in attendance during the last two or three months on some poor creature who thought that her symptoms were "only due to the change."

It is in this relationship of physiological to the pathological in the matter of symptomatology that the early diagnosis of malignant disease of the uterus is difficult. In the case of the breast we have an organ easily accessible even to unskilled investigation. The smallest nodule is frequently noted first by the patient herself. It does not matter whether pain or even local discomfort is present. She knows the possible risks and she seeks advice at once. In the case of the uterus there is no such plain indication. Even hæmorrhage does not occur until a certain amount of necrosis and superficial breaking-down of the growth is present. Pain itself is *never* an early symptom and by some, I think correctly, is regarded as an indication that the condition is involving the cellular tissues around the cervix either by inflammatory exudate or by direct infiltration by the neoplasm.

The onset of cancer of the cervix is insidious and the symptoms are at first so trivial and late in appearance, that one can easily understand how they are missed when masked by what patient and even doctor may regard as purely physiological phenomena.

In 1927 the Ministry of Health published statistics which showed that although there is no special age predisposition to uterine cancer, the frequency steadily increases until the age of 60 is passed. Contrary to general belief these figures prove that there is no very clearly defined tendency for cancer to occur at the menopause. The liability is increasing with the passing years, but more than this cannot be said. It is, however, important to note that this increasing tendency coincides with a period in life, the menopause, when irregular and increased uterine hæmorrhage, especially in the multiparous woman, is comparatively common, and this renders the diagnosis increasingly difficult. At the commencement and end of sexual life in woman, irregular hæmorrhages from the uterus are common. In the adolescent this as a rule is not very important—and certainly not from the point of view under discussion. But to the woman approaching or at the climacteric, with the chance of uterine cancer ever increasing, these hæmorrhages assume a different aspect, and call for very careful investigation.

The Menstrual Function.

To understand the reasons for this tendency of the uterus to bleed irregularly and severely at the menopause, it is necessary to refer briefly to the physiology of the menstrual function. Within recent years opinions regarding this function of the human female have undergone radical change. To-day, many look upon menstruation as being the clinical manifestation of two phenomena or factors A and B, which normally coincide. During active sexual life, from puberty to the menopause, a ripe ovum is discharged from the ovary about the middle of each menstrual cycle, usually between the twelfth and seventeenth days. The cells lining the Graafian follicle from which the ovum has escaped then rapidly develop into the cystic structure known as the corpus luteum. This gland as its prime function produces a secretion which stimulates growth of the embryonic type of connective tissue cells of the endometrium, and effects a degree of development in that membrane which converts it virtually into a decidua ready for the ovum should it be fertilised. This growth is dependent upon constant stimulation by the lutein hormone, and if it is withdrawn the endometrium necroses. The fine capillaries are ruptured and hæmorrhage occurs from numerous points on its surface. The lutein hormone is generally regarded as being antagonistic to ovulation, and so long as a normal and functioning corpus luteum is present, further development of Graafian follicles is, as a rule, suppressed. Should fertilisation not occur, the stimulus to development of the endometrium is withdrawn by degeneration of the corpus luteum itself. Artificially this state of affairs can be brought about by excising or destroying the corpus luteum present in the ovary a week or ten days before the date of the usual menstrual period. The menstrual function can be initiated or antedated by such means. To a less extent the same thing happens if a mature Graafian follicle is excised, cauterised, or merely if its secretion is aspirated by means of a syringe, proving that the integrity of the endometrium is dependent upon a follicular hormone, whether it is intact or converted into the corpus luteum. In other words, it appears as though the mature follicular cell of the Graafian follicle produces at least one hormone identical with that of the fully developed lutein cell, but that in the fully developed lutein gland the secretion is more concentrated.

---

* An address delivered on Nov. 26th, 1930, before the Halifax Division of the British Medical Association in conjunction with the Yorkshire Council of the British Empire Cancer Campaign.

Further evidence upon the nutritive value or stimulating properties of the lutein secretion upon the endometrium has recently been brought forward by H. F. Traut.[1] Traut found that by using a complex medium of tyrode solution, fibrinogen suspension, and sodium linoleate it is possible to grow endometrium in vitro. By adding corpus luteum extract to the medium cellular growth is considerably stimulated, as against controls containing other tissue extracts. Embryonic extract possesses the same stimulating power, derived I believe from the corpus luteum. Indeed I am gradually coming to the view that the corpus luteum hormone not only stimulates the development of the decidua, but that it is also a natural stimulant to all embryonic connective tissues, and that it probably acts as a vitamin to the developing embryo.

The malignant cell itself is embryonic in type and investigations are in progress in the Cancer Research Department of the University of Birmingham to ascertain the influence of lutein and follicular ovarian extracts upon malignant cells. We all know the rapid progress of malignant neoplasms in the young and especially if pregnancy supervenes. Can this tendency to rapid cell proliferation in the embryo and in malignant growths of the child and young adult be due to excess of the lutein vitamin, inherent in the former and acquired in the latter? Many years ago Sir George Beatson pointed out the advantages of double oöphorectomy in some cases of mammary carcinoma, and herein may lie the explanation.

Another interesting fact is that in the human female the two organs most prone to malignant growths are those directly under ovarian influence—viz., the uterus and the breast. Further, when malignant disease does involve the ovary itself the neoplasm is usually characterised by extremely rapid growth, producing immense neoplasms and rapid peritoneal dissemination. This is what would be expected if a natural growth vitamin was produced or concentrated in the ovary.

INFLUENCE OF ŒSTRIN.

If human menstruation was simply the abortion of a useless decidua, the problem of uterine hæmorrhage would be a comparatively simple matter. There is, however, another factor (B) which materially complicates the situation. I refer to the influence of the hormone "œstrin" or the female sex hormone about which so much has been written during the last few years. Menstruation, such as we know it, is accompanied by general and local hyperæmia. It is characterised by secretion of the uterine glands, both corporeal and cervical, and evidence of thyroid activity. The initiation and maintenance of this phase of menstrual activity I attribute to the action of œstrin. The function of œstrin is, of course, to produce a state of œstrus, a provision of nature to promote fertilisation at the next ovulation (post-menstrual). Œstrus, common to most organisms as far as we know, but subject to variation as to time in the sex cycle in different families and genera of the animal kingdom, coincides in the human species with the abortion of the useless decidua. In other words, factors A and B normally synchronise.

The menstrual function has been regarded by some as a preparation for pregnancy. This is correct in so far as factor B, the œstrin factor, is concerned. Others, and not a few lay minds, consider it to be possibly an excretory process. This can only be right if the outpouring of useless calcium and iodine from the uterine glands in the process of menstrual abortion can be so regarded.

What is the source of the sex hormone in the body? It is commonly, of course, supposed to be the ovary and, indeed, is described by many writers and workers as "the active principle of the ovary." The reason for this is that the earlier investigators first described the hormone as a constituent of the fluid follicular contents of the ovary. Later it was found in the ovarian stroma, but *not* in the corpus luteum. It was then discovered that the placenta contained large quantities of the active principle, and to-day, through the work of Loeb, Zondek, Aschheim, and others we know that it is present in many body fluids and organs. The urine of pregnant women contains an abundance of the sex hormone, and essential quantities are also present in the blood, liver, bile, and fæces during pregnancy, in spite of the fact that ovulation is supposed to be suppressed by the corpus luteum! Plants also show the presence of an active principle which possesses a similar action to the female sex hormone. The commercial source of most of the effective œstrin on the market is, I believe, either the placenta or the urine. For these reasons the term "ovarian hormone" appears to be a misnomer.

ŒSTRUS AND OVULATION.

An interesting and important observation of Zondek is that, by means of thallium, it is possible in animals to stop the production of the sex hormone even when follicles with ripe ova showing mitotic figures are present. Therefore, the sex hormone does not control the growth and activities of the ovum. On the other hand, in young animals by the injection of follicular fluid or other sex-hormone-containing substance, it is possible to produce complete œstrus in the absence of any ripe ova. In animals such as the mouse and rat all ova can be destroyed by means of X rays, and yet œstrus can be artificially established by injections of the œstral hormone. Experiments such as these prove conclusively the absolute independence of ovulation and œstrus. In the human female both functions, whilst independent, are coördinated by Nature to promote the highest degree of fertility.

Since both factors coincide, it naturally follows that the hæmorrhage of menstruation, whilst normally resulting both from necrosis and hyperæmia of the endometrium, *may be caused by one factor only.* If œstrus is sufficiently intense the hyperæmic endometrium will ooze independently, whether any necrosis is present or not. Indeed, ovulation may be entirely suppressed, and the individual is, of course, sterile, even though a slight œstral menstrual bleeding regularly occurs. Similarly, œstrus may be entirely absent, and the uterus will still bleed if ovulation takes place, and the endometrium necroses in the absence of fertilisation.

It is important to note, therefore, that a slight uterine hæmorrhage may represent œstrus without ovulation or ovulation without œstrus. Conversely, a long and protracted bleeding can be the result of endometrial necrosis with intense hyperæmia from excessive production of œstrin. If this view is accepted it appears to dispose of the criticisms of G. W. Corner and the late Prof. J. H. Teacher as to the relationship of menstruation to ovulation.

It is remarkable fact in Nature that physiological activity related to the sex function, follows in the majority of organisms, both high and low, a cyclical curve. The basic factors which underlie this phenomenon are unknown. We do know, however, that the general metabolic processes in the human female appear to be definitely related to the cyclical rhythm of the sex function. This is shown by variation in the bodily temperature, the calcium and iodine content of the blood, the pre-menstrual raised ammonia co-efficient, and the basal metabolic rate. The latter is particularly interesting, and one of my students, Dr. K. Roberts, has shown that a curve can be drawn of the basal metabolic rate, which automatically divides itself into four phases corresponding closely to the various stages of endometrial development. At and after the menopause this cyclical rhythm is still maintained for a time in the absence of any hæmorrhagic uterine discharge. Even when uterus and ovaries are removed, the subsequent metabolic curve continues to show the usual menstrual disturbance, although the variations are not so obvious, because the metabolic rate throughout the cycle is continually high.

If an artificial menstrual period is initiated by destruction of a mature Graafian follicle or developing corpus luteum a disturbance of the basal metabolic rate is produced, which is typical of that described as normal for the natural function. Also, at the time in the cycle when menstruation would normally have occurred, had no surgical interference taken place, a second typical menstrual rise and fall occurs, although unaccompanied as a rule by any uterine hæmorrhage. At the actual menopause ovulation is commonly frequent, irregular, and patchy, and this is reflected by marked variations in the metabolic rate.

How far is it possible to correlate these various observations and experimental facts with clinical data in relation to malignant disease of the uterus?

Post-menopausal Hæmorrhage.

As a woman approaches the menopause, and for some years after, the tendency to cancer of the uterus increases. Also, as the menopause approaches, the discharge of healthy ova from the ovary becomes irregular. Some ova fail to mature, and others take longer than the usual 14 days. In some cases an ovum ripens only at intervals of months; and occasionally a belated reproductive cell does not mature until two or three years have passed after the apparent cessation of the menses. Whenever such an ovum ripens and escapes from its follicle a corpus luteum develops in the corresponding ovary, and the *endometrium finally necroses with the production of* bleeding.

I have seen a recent corpus luteum in the ovary from a woman aged 67 removed with the uterus on account of post-menopausal uterine hæmorrhage where cancer was suspected but non-existent. Many of these occasional post-menopausal hæmorrhages can probably be explained by delayed or late ovulation. In itself, uterine hæmorrhage due to this cause is quite harmless, but when it occurs it generally necessitates a diagnostic curettage owing to the possibility of the bleeding being caused by an early carcinoma of the uterine body.

The type of hæmorrhage, however, commonly gives quite useful diagnostic information, that caused by late ovulation being in character and duration very like an ordinary menstrual period. Some patients note this themselves. The bleeding from a uterus, the seat of carcinoma of the corpus, is smaller in amount, bright red, and more prolonged. It is a slight irregular or continuous blood-stained discharge rather than a single short solitary hæmorrhage. The occurrence of such a continued or intermittent red discharge in a woman over the age of 40, whether nulliparous or multiparous, is always a most dangerous symptom. It is a matter of no concern whether the uterine body is enlarged or not, for carcinoma affecting this site occurs in at least two well-defined pathological types. In one the growth produces a tuberous type of neoplasm with greater or less uterine enlargement. This is the more common type, and bleeding is not infrequently absent until the neoplasm has made considerable headway in involvement of the uterine wall. Even when it does occur it is so slight that patients often do not seek advice until the discharge has been present for several months. A short, sharp hæmorrhage, the result of late ovulation, is much more likely to bring a woman under medical observation *than this trivial blood-stained discharge* associated with a developing cancer of the uterine body. We cannot, therefore, give better advice than to impress upon every woman the supreme importance of obtaining advice immediately she notices *any* blood-stained discharge from the genital passage, no matter how slight, once the menses have ceased.

In the second and rarer pathological type the neoplasm assumes a papillary form, either diffuse or localised as a polypus. Here, again, the type of hæmorrhage is an irregular or continuous blood-stained discharge, but it occurs earlier and the discharge contains more blood. Such types although rarer are seen earlier, because hæmorrhage is more pronounced. In both, clots are rarely a feature of the bleeding until the growth has reached such dimensions that diagnosis is an easy matter. On the other hand, clots are not infrequently passed when hæmorrhage is associated with non-malignant conditions of the uterine body.

ADENOMATOUS UTERINE POLYPUS.

There are several conditions which cause post-menopausal hæmorrhage quite apart from late ovulation to which I have referred. One is the simple adenomatous mucous polypus of the endometrium. This occurs at all ages from puberty onwards. I have removed one from a girl of 19 and another from a woman of 83. I am much interested in these little uterine polyps and have often thought over their genesis. A polypus of simple type is a localised endometrial hypertrophy. Now hypertrophy of the endometrium is associated with what may be termed diminished intra-uterine tension. Under normal conditions—i.e., in the healthy uterus—the uterine cavity is practically non-existent owing to approximation of the anterior and posterior walls. With the development of pro-œstrum and swelling of the pseudo-decidua the intra-uterine tension is naturally increased, and this tension is not released until necrosis of the superficial layer or stratum compactum has occurred.

In certain pathological states the uterine cavity remains permanently enlarged, and the intra-uterine tension is correspondingly lower. In a uterus the seat of chronic subinvolution, for example, the uterine cavity is increased in all dimensions. The result is a uniform overgrowth of the whole of the endometrium until the cavity is obliterated and presumably the intra-uterine tension is again raised to the normal level. The same thing occurs in a uterus where the cavity is enlarged and distorted by multiple interstitial and submucous fibromyomata. Where the walls are in contact the endometrium is of normal growth or atrophic. Whenever a cavity is produced, however, the endometrium either undergoes diffuse growth or develops a polypus in an attempt to obliterate the same. It seems as though the organ abhors a vacuum, and therefore the normal intra-uterine tension probably exerts a not unimportant influence upon the degree of regeneration of the endometrium which ensues upon the termination of the pseudopregnant state. This tension is normally maintained by the tone and state of development of the uterine muscle. Diminished tone will favour endometrial overgrowth. The genesis of the simple adenomatous polypus appears therefore to be intimately associated with this same factor of tension. Not only is the major factor of intra-uterine tension as a whole involved, but also the local tissue tension. This naturally varies with the periodical growth of the endometrium dependent upon the ovarian hormone, and the amount of molecular necrosis which occurs at the end of the menstrual cycle. If the necrosis is irregular and patchy, as is frequently shown by curettings to be the case, the subsequent regenerative phase must introduce local variations in tissue tension, which find their expression in corresponding overgrowths. Once this pathological process is initiated a vicious circle is produced which will tend to be perpetuated, and may introduce by the same method the element of malignancy. Indeed several polypi have been removed which actually show a transition from simple to malignant characters.

When these simple polypi develop before the menopause, as the majority do, they commonly exhibit pre-menstrual congestion or actual superficial necrosis *after* the rest of the endometrium has passed into a state of post-œstrum and is undergoing a process of regeneration. A polypus, under such conditions, might almost be said to represent a state of post-maturity, and as such is a causative factor of menostaxis or prolonged menstrual hæmorrhage. Occasionally necrosis does not occur until the termination of the normal hæmorrhage from the rest of the endometrium. The bleeding is then apparently metrostaxic, although in reality the basis of the hæmorrhage is laid during the preceding menstrual cycle. Post-menopausal hæmorrhage from a simple adenomatous polypus appears to be the result of simple venous congestion due to constriction of the pedicle by increasing fibrosis.

VALUE OF CURETTAGE.

The type of bleeding which an adenomatous polypus produces is very similar to that from an early carcinoma of the uterine body. It is a blood-stained discharge with in some cases a rather more severe bleeding which frequently first brings the patient under observation. Unless the polypus is actually protruding through the cervical canal, and appearing at the os externum, the actual diagnosis can only be made by means of the curette and the microscope. The same applies to such other causes of post-menopausal hæmorrhage as papilliferous adenoma, and so-called senile endometritis. Indeed, in practically every case of post-menopausal hæmorrhage the only safe course to adopt is careful exploration of the uterine cavity, should the cause of the bleeding not be obvious from a preliminary investigation of the lower genital tract and the cervix uteri. The only exception that I would make, and I agree that this is open to criticism, is in certain cases where a single short hæmorrhage occurs, menstrual in type and character, and not repeated. Such a symptom *may* be due to late physiological activity of the sexual system or to a sudden flushing of the senile endometrium from certain general causes. In some few cases of hæmorrhage that conform to this type I have postponed diagnostic exploration of the uterine cavity and, as circumstances subsequently proved, correctly. I have always felt, however, that I have been playing with fire, and whenever real doubt exists I do not like to *think*. I like to *know*, and this attitude of mind generally decides the policy.

Criticism has been raised by some as to possible risk in a diagnostic curettage of disseminating the growth, and the suggestion has been made that the discharge itself should be examined for the presence of malignant cells as a safer alternative. I have tried this method of aspirating the uterine cavity and examining the contents of the pipette, but in my experience it is unreliable. Furthermore, I believe that the supposed danger is theoretical, and I know of no instance where dissemination of a corporeal growth can be definitely laid at the feet of a previous diagnostic curettage. Sometimes, in the ordinary course of dilatation of the cervix, fragments of tissue from a friable growth escape from the cervical canal. These are quite sufficient for the purpose of diagnosis, and there is no necessity to proceed and scrape the whole of the uterine wall to obtain more material. Curettage at all times should be a delicate operation, and when carcinoma of the uterine body is suspected, very careful handling is required. The uterine wall in some elderly subjects is as soft and friable as wet blotting-paper, and the heavy hand can do much damage. The same applies to the casual use of the uterine sound, an instrument which should be discarded where the question of the diagnosis of uterine cancer is concerned.

Menopausal Hæmorrhage in Relation to Uterine Carcinoma.

Post-menopausal hæmorrhage, therefore, need not necessarily be associated with any great difficulty in diagnosis once the case comes under observation. All bleeding of this type is abnormal and every case calls for very careful scrutiny. The diagnosis should be carcinoma, until the contrary is proved. During the years of the menopause itself, however, difficulties constantly arise, owing to variations in the normal menstrual function. Some of these variations have a purely physiological basis; others are associated with local uterine or ovarian lesions.

EPIMENORRHŒA.

As a woman approaches the end of her sexual life, local changes take place in the uterus and ovaries which favour the occurrence of abnormal hæmorrhage.

To take the ovaries first; these organs have discharged the majority of their germ cells, and the few that remain either do not mature or escape at irregular intervals. Sometimes several ova are discharged at the same ovulation, as shown by the presence of more than one corpus luteum. In some women there appears to be a speeding up of ovulation at or about the age of cessation of the reproductive function. This "mass production" of reproductive cells causes a temporary increase in fertility, and in certain cases the one and only pregnancy occurs at this time. Irregularity in the maturation and discharge of ova at the menopause is reflected by corresponding alternating periods of amenorrhœa and hæmorrhage on the part of the uterus. This irregularity is intensified in some cases by the fact that œstrus and ovulation appear not to synchronise as normally. Such women experience two short periods in the cycle, the natural rhythm being upset. It is not surprising, therefore, that confusion should arise in the early diagnosis of carcinoma of the uterus. Women know that the menopause is at times characterised by irregular bleeding of this type, and therefore, unfortunately, they do not take mere alteration in rhythm as a serious symptom.

Irregularity in function is, however, not the only anomaly of menopausal hæmorrhage. Two other types of bleeding are of frequent occurrence. One is "flooding," or what we may call a true "menorrhagia." The other is a prolonged bleeding which may not be serious as a symptom, but which *in itself* is more dangerous, as it closely resembles the type of hæmorrhage from a carcinoma of the cervix. This type of bleeding I label under the term "menostaxis."

MENORRHAGIA.

Menorrhagia or "flooding" appears to be the result of a local atrophy or in some cases an inflammatory reaction of the uterine wall, both muscle and endometrium. The normal muscle is replaced by fibrous tissue, and the contractile power of the organ is seriously handicapped. Inasmuch as muscular contractions play an important part in controlling the uterine circulation at each menstrual abortion, fibrosis of the organ is associated with severe menstrual hæmorrhage, amounting sometimes to serious "floodings." In the multiparous woman, with a uterus enlarged by chronic subinvolution, menorrhagia at the menopause is very common, and since the bleeding is severe, such patients usually seek advice at an early date. If the cervix happens, in addition, to be deeply lacerated, the lips everted, thickened, hard, and irregular from chronic inflammatory fibrosis, I can well understand how difficulty in diagnosis arises. Further reference to this type of cervix will be made, but at this stage I would have you *note that a true menorrhagic type of* bleeding at the menopause, or in common parlance "flooding," is not usually associated with carcinoma of the cervix—certainly not in its early stages. Patients with fibrosis uteri associated with irregular and severe uterine hæmorrhage usually pass large clots in the discharge, and soon show a greater or less degree of secondary anæmia. This is not so with carcinoma of the uterus, either body or cervix, in the early stages of the disease when diagnosis is difficult. In the late stages the local physical signs are so marked that the diagnosis is obvious.

MENOSTAXIS.

The third type of menopausal hæmorrhage, the lengthy or drawn-out menstrual period—*menostaxis* as I prefer to call it, is a much more important symptom in the diagnosis of uterine carcinoma. It, indeed, very closely simulates the paroxysmal bleeding from an early malignant neoplasm of the cervix.

The cause of menostaxis at the menopause is, I believe, partly associated with the presence of dead and immature ova in the ovary (fibrocystic ovaries) and partly with local abnormalities in the endometrium. It is possible to produce this type of uterine hæmorrhage artificially by destroying partially mature Graafian follicles in the middle of the menstrual cycle. It frequently occurs clinically when a diseased uterine appendage is removed or partial oöphorectomy performed.

The normal relation of the endometrium to the control of hæmorrhage is somewhat complicated. I take the view that both stroma and glands of the uterine body have a part.[3] Clotting is promoted by the presence of thrombokinase in the cells of the stroma and this thrombokinase is liberated as the normal endometrium breaks down. Necrosis also sets free the pent-up secretion in the glands of the uterine body running obliquely in its walls. The secretion of the glands contains a thrombolysin, which dissolves the "menstrual clot" or abortion, and facilitates its removal in the form of the menstrual "lochia."

At the menopause the endometrium is either atrophic, or in the case of the subinvoluted uterus, hypertrophic. In either event a factor is introduced which tends to make such menstrual bleeding as occurs both severe and prolonged. If the endometrium is atrophic or fibrosed there is no mechanism to control bleeding. Thrombokinase is deficient and a local state of hæmophilia exists. On the other hand, if the endometrium is hypertrophic, the normal and natural necrosis is patchy and on a very extensive scale, and a large amount of thrombolysin is discharged by the uterine glands. In either case the menstrual hæmorrhage tends to be considerably prolonged. If such a local condition of the uterus is complicated by irregular ovulation, the clinical picture very closely resembles that presented by carcinoma of the cervix uteri.

METROSTAXIS.

It is true that careful scrutiny of the symptom will sometimes give a lead in the matter of fine diagnosis in these difficult cases between a benign and a malignant cause of bleeding. The occurrence of so-called menstrual molimina or those symptoms associated with the "negative phase" of the menstrual cycle for example, naturally suggest that irregular and prolonged hæmorrhage may be the result of uterine "insufficiency" rather than a neoplasm. Similarly, if it is possible actually to investigate the discharge, the colour and other characters may be *more typical of the menstrual lochia than the hæmorrhage* from a cervical carcinoma. From a practical point of view, however, such diagnosis based on symptoms is rather too theoretical and "hair-splitting." The problem at stake is too serious to gamble upon possibilities, and the only straight and safe course to adopt is to insist upon a local, and if necessary, microscopical examination of the cervical tissues in *every* case of irregular bleeding from the uterus.

I do not want to suggest for one moment, because I have ventured to analyse the types of hæmorrhage that occur at the menopause, and to attempt an explanation of the manner of their genesis, that I do not lay stress upon the importance of a local pelvic examination whenever suspicion arises. And this local examination must not in any way be superficial. At its conclusion we must be able to say definitely, without doubt or equivocation, that the patient has not a malignant growth of her uterus. This is not always easy without the aid of anæsthesia, especially in the case of those early intracervical neoplasms growing in relation with the supravaginal cervix. The tissues of the vaginal cervix are not always hard or indurated when a supravaginal carcinoma exists. Neither is the os externum always irregular or its edges friable. If, however, on combined bimanual rectovaginal abdominal examination the cervix appears to be unduly bulky or "barrel-shaped," no time should be lost in dilating the cervical canal and exploring digitally, or perhaps with the curette, the tissues of the supravaginal cervix. In some instances of a neoplasm in this situation, the vaginal cervix when exposed by a speculum appears to be almost atrophic and cicatrised.

Coitional Hæmorrhage.

I have now referred in general terms to four types of uterine hæmorrhage, associated with the menopausal and post-menopausal epochs in relation to uterine carcinoma: epimenorrhœa, or too frequent periods; menorrhagia, or excessive periods; menostaxis, or prolonged periods; and metrostaxis, or hæmorrhage unassociated with menstrual factors.

In connexion with the latter there is one form of uterine bleeding which, in conclusion, I wish to emphasise as being a most important, perhaps the most important, diagnostic sign of all. I refer to the hæmorrhage which occurs as a direct result of coitus. Coitional hæmorrhage must always be regarded with the greatest suspicion. It is true that a blood-stained discharge, or in some cases slight actual hæmorrhage sometimes follows coitus, when the cervix is the seat of an extensive erosion and ectropion, or when a simple polypus is projecting through the os externum. A severe bleeding associated with coitus, is, however, nearly always evidence that cervical carcinoma exists, and a very careful examination of the cervical tissues is demanded. A bimanual investigation of the uterus and appendages is first conducted, and the consistence, shape, and size of the uterus, both corpus and cervix, noted. The cervix is then thoroughly exposed by means of a speculum, preferably Sims's, or one of its modifications, and with the aid of good illumination the tissues carefully inspected.

If a polypus is present it is twisted off and sent to a pathologist for report. If an erosion or ectropion is seen, the surface may be lightly touched with a dressed Playfair probe. In the case of the "papillary" type of erosion, oozing of blood is readily produced by such means from the bright red granular surface. It occurs, however, from numerous points and is slight in amount. From a carcinomatous ulcer or early "cauliflower" growth the hæmorrhage on contact is much more free, and the cervical tissues darker in colour. When the cervix has suffered severe trauma during parturition it is not uncommon for the torn lips to undergo considerable hypertrophy and eversion. This condition of ectropion, frequently associated with a hypertrophic adenomatous state of the cervical epithelium, which bleeds slightly on contact, closely simulates cancer. The tissues, however, are not friable. Should any doubt exist, the correct procedure is to proceed at once to a biopsy. Vernon Bailey,[2] in an excellent piece of work, has recently shown the very close relationship that exists between erosion and ectropion of the cervix and malignant disease. Both these condition are entitled to a well-earned position in that community of suspicious characters comprised by th term "pre-cancerous states," and as such are deservin of more respect than is sometimes accorded to them Amongst maternal disabilities I place ectropion o the cervix high in the list, and my own practice i either to amputate or repair by the Schroeder o Sturmdorf technique any cervix which presents a all a gross lesion of this type.

I will conclude with the same theme with which I began—viz., the importance to-day of continuing to impress upon all women of advancing years the danger they incur of neglecting irregular, frequent, or continued hæmorrhage from the genital tract, however slight it may appear. Let us not be afraid of developing a state of cancerophobia, but rather deliver a renewed attack upon that pernicious lay doctrine that all such symptoms are probably "only due to the change." I personally cannot forget that stream of inoperable uterine cancers that recently passed through my clinic in the short space of only 12 months because the unfortunate women held this belief.

SURGICAL TRAUMA AND CONVALESCENCE.*

BY J. BASIL HUME, M.S. LOND., F.R.C.S. ENG.,

DEMONSTRATOR OF OPERATIVE SURGERY, ST. BARTHOLOMEW'S HOSPITAL.

SURGERY, however successful it may be from the point of view of the eradication of disease, must of necessity be associated with some injury to the patient in the process of effecting a cure. The degree of injury inflicted undoubtedly influences the rapidity of recovery, because although the wound heals and the patient leaves his bed, an interval, often a considerable one, elapses before he is able to return to work, while a still longer period elapses before he is absolutely fit again. This period of delayed convalescence is greater in women than in men, and in nervous subjects than in placid or normal ones.

Convalescence may be divided into two stages: a primary stage, extending from the time of the operation to the time when the patient begins to return to ordinary life, and a secondary stage, from this time until complete fitness is attained. Delay in convalescence, whether primary or secondary, is due to two particular factors: first, the actual amount of injury inflicted at the operation, and second, what may be termed psychological or nervous factors. It is obvious that recovery from extensive abdominal operations is slower than from operations on the extremities or simple abdominal operations. The psychological or nervous factors are much more difficult to define, but an operation is undoubtedly associated with an "insult" to the nervous system.

---

* An address given to the Hampstead Medical Society on Nov. 20th, 1930.

Preliminaries of Operation.

Any operation is preceded by a perfect array of unpleasant preliminaries, many of which might be avoided. First comes the full dose of castor oil, which nurses at any rate consider to be quite essential. This over-stimulates the intestinal wall, produces congestion of the mucosa, and dehydrates the patient. My own experience indicates that there is much less post-operative discomfort from distension of the intestine with gas when no violent purge has been administered. Second comes the period of pre-operative starvation, beginning usually at 4 or 5 P.M. on the day before operation. As a matter of fact, patients need both sugar and water in considerable quantities in this period and, except in cases of pyloric obstruction associated with dilatation of the stomach, fluid should be given up to two hours before the operation. If the patient is in urgent need of fluid and sufficient quantity cannot be given by the mouth, rectal administration may be used. The most satisfactory way of giving sugar is in the form of barley-sugar or glucose lemonade.

The patient should, if possible, have an absolutely undisturbed night before the operation. The toilet of the abdominal wall should be completed in the early evening, and a mild sleeping draught, such as bromide and aspirin, should be given so that he may not lie awake brooding on the supposed horrors of the morning. Fear of the operation and of the anæsthetic is a very real thing with the majority of patients, though few would confess it. In particular, they complain of the dread of being suffocated by the anæsthetic, a fear that, unfortunately, has more than a basis of truth, as it often arises from actual unpleasant experiences with gas when in the dentist's chair. Patients need reassuring on this point, but especially they need the pre-operative sleep which should on no account be disturbed at an early hour.

The last straw, especially after a disturbed night, is the effort of preserving a brave and often cheery appearance in the anæsthetic room or while waiting on the operation table for the anæsthetist to prepare his apparatus, try on the mask, and fill his bottles.

When one considers the pre-operative treatment in this light it is readily apparent that unwise preparation reduces the vitality of the patient, increases the liability to post-operative shock, and gravely affects the condition of the intestinal wall in abdominal operations, while the nervous strain will undoubtedly prolong the second stage of convalescence and in some cases even produce a permanent neurasthenia.

Abdominal Insult.

There is, in addition, another subtle nervous factor in abdominal operations, a much less understood process which can only be referred to as an "abdominal insult." A mere exploratory operation, when nothing is done beyond opening the peritoneal cavity and examining some of its contents, is often followed by a period of convalescence which in both its primary and secondary stages is equal in length to a convalescence after some major operation. On the other hand, some appendicectomies performed through small incisions are followed by a very short convalescence. Perhaps the shortness of the incision and the absence of any extensive manipulation of the abdominal contents are physical factors which may account for the difference, but the after-effects of the "look and see" type of operation should deter any surgeon who considers the well-being of his patients. Even such a simple operation as an appendicectomy, if it is performed without some definite and well-proven lesion of the appendix, is likely to be the starting-point of a train of symptoms which may be difficult or even impossible to cure.

Every surgeon is familiar with the lady with two or three or more scars on her abdomen, who comes in all eagerness for yet a further operation. If he consents he is merely storing up trouble for himself in the future and breaking one of the cardinal rules of medicine—"Thou shall do thy patient no harm." To such people an unnecessary abdominal operation is a real calamity, since it confirms them in their subconscious view of the physical reality of their complaints, and immensely complicates, if it does not actually wreck, their chance of future well-being.

Many physical factors are, of course, concerned in surgical trauma. Such things as imperfect hæmostasis or devitalisation of muscle lead to the entrance of toxic substances into the circulation; while rough handling of the abdominal wall by retractors, pulling on the viscera, and crushing or pinching of bowel stimulate the sympathetic nerves. These are well-known causes of surgical shock, but fortunately not every operation is followed by surgical shock to a recognisable degree. Even when great care and gentleness are displayed, however, there must be some absorption from the wound and some over-stimulation of the sympathetic.

Severe operations on the upper abdomen, such as gastrectomies, are always associated with a very considerable amount of shock unless care is taken to avoid the more obvious causes of surgical trauma, and unless such precautions as nerve-block or infiltration of the splanchnic nerves are undertaken.

After-treatment.

Even when there is no recognisable degree of shock the patient should receive treatment directed towards combating it. The bed should be warm, a rectal saline containing 5 per cent. of glucose and grs. 20 aspirin should be given, and if pain or restlessness are present they should be relieved by an injection of morphia or omnopon. The treatment during the primary stage of convalescence is very important. Many surgeons seem to be obsessed with the likelihood of their wounds bursting open, or at any rate, producing a post-operative hernia. On this account patients are kept on their backs and tight bandages are applied to the abdomen. To maintain this sort of position for the ten days or so which are supposed to be necessary for the complete healing of the wound must be a strain on the fortitude of the hardiest. An abdominal incision should be so constituted as to obviate as far as possible any accident of this sort and, provided the peritoneum is accurately sutured and nerves supplying muscle or portions of muscle are not divided, there should be no danger of a post-operative hernia.

The natural processes of repair seal off the peritoneal cavity in 48 hours. During the first 48 hours the patient will naturally remain as quiet as possible, partly from weakness after operation and partly on account of the pain which follows movement. Bandages during this period should be sufficiently tight to give the patient full support during vomiting (should that occur) or during coughing, but not tight enough to produce an uncomfortable feeling of constriction. They may require adjustment twice in the day, as in the second 24 hours a amount of abdominal distension from gas is the usual occurrence. We have all grown up with the idea that bandages should not be altered unless the patient finds them absolutely intolerable, or until the abdomen is stretched almost to bursting point. This is, of course, absurd. After the first 48 hours the patient should be allowed to move his limbs in bed, and in the great majority of cases, unless he is being nursed in the Fowler position on account of peritonitis, should be allowed to spend periods of time lying on one side or the other, suitably supported with pillows to the back. Encouragement of movement in bed and deep-breathing exercises will do much to prevent that stagnation in the femoral and iliac veins which predisposes to the formation of a thrombus and to subsequently pulmonary embolism.

Just as castor oil before operation should be avoided because it depletes the patient of important body fluids and because the distension of the bowel by gas often makes manipulations more difficult than they ought to be, so it should be avoided in after-treatment. The regular use of an intestinal lubricant such as liquid paraffin combined with phenolphthalein or cascara, as soon as post-anæsthetic vomiting has stopped, will obviate the use of castor oil. A turpentine enema after 36 hours is usually successful in obtaining an action of the bowels, and a rectal tube should be passed before the enema if meteorism is at all marked.

Perhaps the most important factor in expediting recovery is the use of massage or bed exercises. Many patients when they have spent ten days on their backs suffer from a mild sacro-iliac strain which causes an unpleasant, dull pain in that region. This is almost certainly due to a straightening out of the lumbar curve. It will be avoided if the patient is nursed on the side from time to time, or if the back is massaged. A patient who has been confined to bed for 16 days after an operation on the upper abdomen, but has had regular massage to the back and limbs, should be able to walk as soon as he puts his feet to the ground. Too many patients regard massage as a luxury they think they cannot afford, but they would more than save the masseur's fee in the reduced time they would have to spend at a seaside hydro.

Pre-operative Medication and Choice of Anæsthetic.

I believe that we can save our patients a great deal by the use of suitable pre-operative medication. Morphia, or morphia and hyoscine, will usually allow the patient to go to the operating theatre in a semi-drugged condition in which he does not care very much what happens. Nevertheless, while the drug is taking effect he is still fighting the fear of the unknown.

I have been greatly impressed during the last year, in my own practice, by the narcotic avertin. It was originally claimed for avertin that it would produce complete anæsthesia. This is an over-statement, because it is always necessary, if safe doses are used, to combine it with a local anæsthetic or with gas and oxygen, or both. Why, then, use avertin? Because, if it is successfully given, the patient will go to sleep in bed quite naturally and, if necessary, entirely unaware that the operation is going to take place that morning. My own custom with very nervous patients is to obtain the patient's consent to operation and to ask him to leave the actual day and time in my hands, and then to inform no one in the ward except the ward sister. In the course of the pre-operative treatment the patient receives each morning a rectal injection of normal saline, but on the morning fixed for operation avertin is substituted; the patient is completely deceived and, furthermore, experiences no unpleasant effects in going off to sleep. The technique has been elaborated by Dr. I. N. Lewis, whose valuable assistance as anæsthetist I have had at St. Andrew's Hospital, Dollis Hill. The dose of avertin is calculated as 0·045 g. per pound of body-weight, and about two-thirds of this dose is run in as quickly as the patient will tolerate it. This usually takes 5 minutes. After 10 minutes the patient is tested for replies to questions, and again after 15 and 20 minutes. Between these three times Dr. Lewis has been able to judge very accurately the reaction of the patient to avertin. In general, drowsiness at 10 minutes indicates susceptibility, between 15 and 20 minutes is normal, and longer than 20 minutes indicates resistance. A supplementary dose is then run in, its quantity depending upon the estimation of the patient's requirements made from the previous observations.

In some instances only local infiltration with novocain was used in addition to the avertin, but more satisfactory results were obtained when the avertin was supplemented by gas and oxygen. In no case was it necessary to use ether or chloroform, and the almost complete absence of post-operative vomiting was most satisfactory.

The cases upon which it has been tried have been principally thyroids, and many of the patients have not known that the operation has been performed until they have discovered bandages round their necks later in the day. Brief details of three cases of exophthalmic goitre may be of interest.

A nervous young woman of 20, suffering from exophthalmic goitre, had a basal metabolic rate of + 48 and required a large dose of avertin (6 g.). A bilateral partial thyroidectomy was performed and she made a satisfactory recovery from the immediate effects of the operation. Thirty-six hours later, however, she bled into the cavity, owing to the slipping of a ligature. Under the pretext of giving her a saline, a dose of 5 g. of avertin was run in, an allowance of 1 g. being made for non-excretion of the previous dose. She passed into a quiet sleep and was removed to the theatre, the bleeding point was ligatured, and to this day she is unaware that she made anything but an uninterrupted recovery.

In the other two cases, some months before thyroidectomy, the tonsils had been removed under avertin and gas and oxygen anæsthesia. A prominent feature of that episode was the absence in each case of any soreness of the throat. So pleased were the patients with their experience on that occasion that, although both were very definitely hyperthyroid, they came back for the major operation with gratifying equanimity and both made splendid recoveries.

Avertin, therefore, entirely abolishes the fear of going to the theatre and the unpleasant nature of the induction of a general anæsthetic.

While the idea of some form of rectal anæsthesia is by no means novel, avertin has a great advantage over its predecessors (rectal ether and paraldehyde). These were not without danger, either locally to the mucosa of the rectum or to the patient's general condition, and both are associated with an unpleasant post-anæsthetic odour. Provided that avertin is only used in sufficient doses to produce sleep and some degree of analgesia, it is devoid of these drawbacks. A further advantage is that post-operative vomiting is very considerably lessened. This is probably due to the fact that it is never necessary, even in abdominal operations, to supplement gas and oxygen with either ether or chloroform, and many patients complain that it is the persistent odour of these two substances that nauseates them. Out of a personal series of 20 thyroidectomies and ten other operations, 25 cases were entirely without post-operative vomiting, and in all the rest it was very slight.

If avertin is so satisfactory, why is it not more generally adopted? It requires the attendance of the anæsthetist half an hour before the operation and, as the patient continues to sleep for several hours after it is over, it is advisable for a nurse to be in fairly constant attendance. These, however, are only objections to its use in hospital work, and not in private practice.

Many things, kind and unkind, have been said about nursing homes and institutions. The doctor must remember that he leaves his patient entirely at the mercy of the nurse who chances to be in charge of that particular room, for whereas the patient can choose his doctor or his surgeon, he cannot, as a rule, select his nurse. I do not mean to infer that the majority of nurses are not good, or that they are not in the main models of sympathy and of tact, but a nurse who may be entirely suitable for one patient may drive another to the edge of a nervous breakdown. Nurses may be tyrannical or merely uncongenial, and occasionally they are not experienced in a particular type of case and are, therefore, inefficient. It may be stated as an axiom that you should distrust and avoid nursing homes where you are never left alone with your patient.

There is, therefore, in some cases, a great deal to be said for the patient's having an operation performed in his or her own home where a selected nurse may undertake the after-care. To suggest operating in a private house seems rather heretical for a surgeon who surrounds himself with all the modern aseptic ritual, but, after all, very good surgery was done in the war under much more difficult conditions than are found in a good-class modern house, and a surgeon should be prepared to make some sacrifice of personal convenience and even be prepared to face actual strain in improvising and operating under not quite perfect conditions in order that the patient may have the inestimable advantage of recovering in congenial surroundings.

Of course, in some cases it is a blessing for the harassed mother of three or four children to be removed to a nursing home for an operation, but this merely serves as an example that nothing in medicine or surgery can be laid down as an unbreakable rule.

Practitioners do not usually err in submitting their patients too early to operation, but when they have decided that an operation should be performed, they must remember, in their management of the case beforehand, to do everything that is possible to lighten the ordeal for their patient. By so doing they will undoubtedly shorten the second stage of convalescence and, should their pre-operative diagnosis have been correct, will have a grateful rather than a neurasthenic patient to deal with afterwards.

BOMBAY MUNICIPAL HOSPITAL.—The report for 1929–30 of the King Edward Memorial Hospital and the Seth Gordhandas Sunderdas Medical College, Bombay, states that the constant overcrowding of the wards has necessitated this increase of the beds from 334 to 354. Of the 8575 in-patients under treatment during the year 3690 were cured, 2775 were discharged relieved, 865 "either absconded or left the hospital against medical advice," and 917 died—270 within 24 hours of admission, 165 after 24 hours and within three days, and 481 after three days; one was a stillborn child. The need of an infirmary for chronic and nervous cases is illustrated by the fact that 200 patients had to be kept in the hospital for a period exceeding two months, as against the average stay of 15 days. There is insufficient space and staff for dealing rapidly with the growing number of out-patients.

MUTATION AND PATHOGENICITY EXPERIMENTS WITH B C G.

(From the Sir William Dunn School of Pathology, Oxford.)

(ILLUSTRATIVE PLATE.)

THE strain of *B. tuberculosis* known as "Bacille Calmette-Guérin" (B C G), isolated in 1906 and cultivated by Calmette on a glycerin-bile-potato medium until it appeared to have lost its original virulence, has been used widely, particularly since 1924, for immunising children and cattle against tuberculous infection. This organism has been the subject of extensive investigation in Europe and America. The enormous mass of literature on the subject need not be reviewed here; it has been partially reviewed and criticised by Calmette (1928), Gerlach (1930), and others. The great majority of the reports, from both the clinical and the experimental points of view, have been favourable—the general conclusion being that B C G is non-pathogenic for experimental animals and for humans, and that inoculation with it brings about an increased resistance to subsequent infection with *B. tuberculosis*, even if it does not confer absolute immunity.

Wilbert (1925) obtained remarkably good results in the immunisation of monkeys with B C G, but Griffith (1930), on the contrary, concluded that "vaccination with B C G has failed to protect monkeys against a virulent experimental or familial infection."

A few investigators, notably Petroff, Branch, and Steenken (1929), Watson (1928, 1930), and Lignières (1928) have found B C G to be more or less virulent, and have pointed out the possible dangers associated with the use of a living vaccine. Furthermore, they do not consider that the results so far obtained justify the extensive application of the vaccine in humans and in cattle. Watson (1928) concludes that B C G "is capable of causing in some guinea-pigs, after a long period of infection and tolerance, a progressive and fatal tuberculosis, which then becomes reinoculable and transferable from animal to animal in serial passage." Petroff, Branch, and Steenken (1929) have succeeded in dissociating B C G into "R" and "S" types; lesions produced by the "R" colonies have a tendency to heal, and may disappear in two or four months. The "S" colony invariably produced progressive tuberculosis in guinea-pigs and occasionally in rabbits. Gerlach (1930), using an "S" strain isolated by Petroff, has been unable to confirm his results. Kirchner (1930) has found that B C G may be virulent for guinea-pigs, but the increase in virulence occurs seldom, and only under special conditions.

Petroff's virulent strain of B C G was produced by growing the culture in media other than the glycerin-bile-potato recommended by Calmette, and his experiments therefore do not invalidate Calmette's claim that B C G grown under the conditions he prescribes is avirulent. Nevertheless, as Petroff points out, "if it (B C G) is to be used as a vaccine, we must bear in mind that the human body is not to be compared to glycerol-bile-potato as a medium for its continued viability and development." If it is found possible to produce virulent variants of B C G by growing it under certain laboratory conditions, it is at least not impossible that similar pathogenic variants may arise at times while the organism is growing under parasitic conditions. The present knowledge of the biology of *B. tuberculosis* is too rudimentary to enable one to predict with any degree of certainty the stability or variability of any property such as pathogenicity, and therefore the use of living cultures for immunisation may be associated with some degree of danger.

Culture Experiments.

In the course of some experiments on the growth of *B. tuberculosis* it was found that a certain human strain which had been propagated on artificial media for several years would grow in ordinary veal-peptone bouillon, prepared as follows:

To 5 kg. of minced lean veal, add 10 litres of distilled water; boil for 30 to 60 minutes. Filter. Add 100 g. Witte peptone and 50 g. NaCl. When the peptone and salt is dissolved, adjust the reaction to pH = 6·8. Boil for 30 minutes. Filter through paper. Fill 500 c.cm. into litre flasks, and autoclave for 10 minutes at 10 lb. pressure.

If the inoculum, instead of floating on the surface, was submerged in the liquid, it grew in the form of small granules at the bottom of the flask, the supernatant liquid remaining quite clear. The initial culture in the depths of the medium grew very slowly, sometimes requiring three to four months before there was any appreciable growth. Subsequent cultures, prepared by inoculating fresh flasks containing 500 c.cm. each of the bouillon with a few granules transferred by means of a pipette grew more quickly, but never very rapidly nor very abundantly. Cultures grown thus in the depths of the medium were occasionally, but not regularly, very much more virulent than cultures grown on solid media or on the surface of liquid media. Details of the experiments on this strain will shortly be published.

The same technique was applied to the growth of B C G and the same granular type of growth was obtained at the bottom of the bouillon flasks. As in the previous case the growth was slow. There was no tendency for the culture to grow at the surface of the medium, even after several months incubation.

In growing cultures in this manner, in veal-peptone bouillon, 500 c.cm. quantities in 1000 c.cm. Erlenmeyer flasks have been used regularly. Very uncertain and irregular results have been obtained with smaller volumes of media in tubes. It is important always to inoculate at least five flasks each time the culture is transferred, since even under apparently similar conditions the rate of growth varies considerably. Cultures grown in this way in the depth of the bouillon are referred to throughout this paper as "deep cultures."

Two strains of B C G have been investigated. The first was a strain obtained in March, 1928, from Captain S. R. Douglas, F.R.S., of the National Institute for Medical Research. This culture had been grown on egg medium or on Petroff's medium for several generations, but up to that time it had been completely avirulent for laboratory animals. This culture, which is referred to as B C G (I) was used in Expts. 1, 2, and 3. The virulence of deep cultures as shown in these experiments was rather surprising, and it seemed important to compare it with similar deep cultures of a strain obtained directly from Institut Pasteur.

Through the courtesy of Dr. Calmette, Institut Pasteur, two cultures on potato were received from the Medical Research Council on Oct. 31st, 1928. One of these cultures was opened and deep subcultures were made in bouillon. The remainder of the growth was scraped off, and used to inject a series of 20 guinea-pigs (Expt. 4). This culture is referred to as B C G 359.

Subcultures were made from these two strains at the following times:—

B C G (I).

March 1st, 1928: Culture received from Captain Douglas.
March 20th, 1928: Subcultured on Petroff's medium.
April 4th, 1928: First deep bouillon subculture from Petroff culture.
May 25th, 1928: Second deep bouillon subculture (used for Expts. 1 and 2).
June 27th, 1928: Third deep bouillon subculture.
August 8th, 1928: Fourth deep bouillon subculture (used for Expt. 3).

B C G 359.

Oct. 3rd, 1928: Culture on potato, received Oct. 31st, 1928 (used for Expt. 4).
Nov. 2nd, 1928: First deep bouillon subculture.
Nov. 20th, 1928: Second deep bouillon subculture (used for Expts. 5, 6, and 7).
Jan. 2nd, 1929: Third deep bouillon subculture.
Feb. 19th, 1929: Fourth deep bouillon subculture (used for Expt. 8).

The technique of preparing the material from the deep bouillon cultures for animal inoculation was as follows:—

The granules were pipetted from the bottom of the flask and centrifuged for about ten minutes to pack the growth in the bottom of the tube. The supernatant liquid was poured off and the sediment scraped out with a spatula and weighed wet. The granules were then ground up in a sterile agate mortar, using the clear supernatant liquid from the same culture for making the necessary dilutions.

The doses used in these experiments, therefore, represent a considerably smaller weight of bacilli than corresponding doses of bacilli which have been dried by pressing between sterile filter paper before weighing, as in Calmette's technique.

When cultures on solid media were used for inoculation, the growth was ground up in sterile saline solution, and the subsequent dilutions were also made in saline.

All the guinea-pigs used in these experiments were bred in the Oxford School of Pathology from a pure white strain. They have been isolated from animals infected with other strains of *B. tuberculosis*, both before and during the experiments. The guinea-pigs used in Expts. 1 and 3 were isolated in one room for the duration of the experiments. The cages were sterilised with lysol, followed by live steam before each experiment.

Cultures from the heart blood were made at the post-mortem examination of each animal inoculated with the B C G cultures, and, as shown in the tables, *B. tuberculosis* was found in most of these blood cultures. The number of tubercle bacilli present in the different cultures varied considerably. No attempt has been made to enumerate them accurately, but the relative numbers are indicated by one or more plus signs. (+) indicates very few individual organisms, less than six being found after one hour's search. + indicates individual organisms in larger numbers, and more readily found. ++ indicates that clumps and small colonies were found as well as individual bacilli. +++ indicates large numbers of clumps and colonies readily found with the low power of the microscope.

In a few cases where the post-mortem examination could be made before the blood had coagulated, smears of the heart blood were made and examined for *B. tuberculosis* directly. The technique of the procedure used for blood cultures and for the examination of the direct smears will be described in detail in another communication shortly to be published.

A striking feature of the post-mortem examination of the guinea-pigs infected with deep B C G cultures was the very high proportion which had tuberculous lesions in the testes or epididymes, whether or not the infection was generalised. Lesions in these organs were much more common than we had observed with any other strain of *B. tuberculosis*, human or bovine, which we have previously used. Tuberculous infection of the testes and epididymes is, therefore, noted in the Tables when found.

TABLE I.—*Second Deep Bouillon Subculture of B C G (I) 34 days old. Guinea-pigs Injected Intraperitoneally.*

Guinea-pig No.	Weight (g.) at—		Dose mg.	Days lived.	TB in blood culture.	Post-mortem.
	Injection.	Death.				
476	363	331	2	33	+ +	G.T.
477	447	350	2	39	+ +	"
478	395	302	2	62	+ +	G.T. Te. TB +
479	396	334	5	33	+ +	G.T.
480	381	231	5	39	+ +	"
481	347	232	5	37	+ +	"
482	457	344	10	39	+ +	G.T. Ut. TB +.
483	425	302	10	25	+	" " "
484	373	251	10	31	+	" " "
485	326	250	20	33	+ +	G.T.
486	357	262	20	40	+	"
487	330	250	20	40	+	"

G.T. = Generalised tuberculosis. TB + *B. tuberculosis* present. Te. = testes. Ut. = uterus.

The term G. T. used in the Tables means generalised tuberculosis. By this is understood extensive tuberculous lesions in lung, spleen, and glands. In the case of the B C G deep cultures the lesions were found in all stages of development, from slight infiltration to extensive caseation, and usually contained enormous masses of tubercle bacilli.

EXPT. 1. B C G (I) June 28th, 1928.—Twelve guinea-pigs were infected intraperitoneally with the second deep *bouillon subculture of B C G (I) in doses varying from 2 to* 20 mg. The culture was 34 days old at the time of inoculation. These guinea-pigs died in from 25 to 62 days. The post-mortem examination showed a severe generalised tuberculosis in each case. Cultures of *B. tuberculosis* were obtained from the heart blood, post mortem, of each *guinea-pig (Table I.).*

EXPT. 2. B C G (I) June 28th, 1928.—Twelve rabbits were injected intravenously with the same deep culture (34 days old) as used in Expt. 1. The doses varied from 5 to 50 mg. The four rabbits which had doses of 50 mg. all died in 11 to 14 days, and No. 203, which had 15 mg., *died in 19 days. These all showed acute congestion and* hepatisation of the lungs. The 7 remaining rabbits all lived over 200 days, and all developed generalised tuberculosis. Two of these rabbits were killed after they developed paralysis of the hind legs, and two others (198 and 201) were killed after they had developed a well-marked tuberculous arthritis. No. 201 is of particular interest, having developed a severe tuberculous arthritis in all legs, with extensive caseation and much fresh granulation tissue. The condition of the joints is shown in the X ray plates and the photographs (Figs. 3–8). Guinea-pig 814 was infected subcutaneously with caseous pus from one of the joints of rabbit 201. It died in 125 days, having generalised tuberculosis. *B. tuberculosis* was present in the culture of the heart blood of this guinea-pig, and was also found in a direct smear of the heart blood (Table II.).

EXPT. 3. B C G (I) August 19th, 1928.—Sixteen guinea-pigs were injected intraperitoneally with the fourth deep subculture in bouillon of B C G (I). The culture was 11 days old at the time of injection. Smaller doses were given than in Expt. 1. The guinea-pigs died in from 36 to 122 days. *All developed generalised tuberculosis, and B. tuberculosis* was again found in all the cultures from the heart blood taken post mortem. In 14 of the 16 animals the testes showed caseous lesions (Table III.).

207	1300	1209	50	11	Lungs hepatised. Liver, numerous abscesses.
208	1105	1023	50	14	Lungs hepatised.

* Killed.

subcutaneously into four fresh guinea-pigs. Three of these developed generalised tuberculosis, and a few healed and healing lesions were found in the fourth one post mortem. Cultures of *B. tuberculosis* were recovered from the heart blood of each of these four guinea-pigs (Table IV.).

Expt. 3b. Nov. 12th, 1928.—Guinea-pig 526 (Expt. 3) was killed 86 days after inoculation and was found to have generalised tuberculosis. Parts of the lung, testis, and omentum were ground up in sterile saline, and the suspensions injected subcutaneously into six guinea-pigs. These all died of generalised tuberculosis, and *B. tuberculosis* was present in cultures from the heart blood of five of the six animals (Table V.).

757	,,	300	324	175	+		G.T.

* Epididymes caseous. † Right testis and epididymes TB +. ‡ Testes caseous.

Expt. 3c. Jan. 2nd, 1929.—Two cultures were isolated from the testes, and one from the lungs of guinea-pig 526. These cultures were made on Petroff's medium, and four guinea-pigs were inoculated with a 10 days' old subculture from each culture; the doses and route of infection are shown in the Table. These 12 animals all died in from 25 to 177 days, having well-developed generalised tuberculosis. Tuberculous abscesses were present in the testes or epididymes of nine of these animals, and *B. tuberculosis* was found in the culture from the heart-blood of nine of them (Table VI.).

Expt. 4. B C G 359 Nov. 2nd, 1928.—Twenty guinea-pigs, Nos. 732 to 751, were injected intraperitoneally with the culture of B C G 359, growing on potato, as received from l'Institut Pasteur. Two guinea-pigs were given doses of 50 mg. each, and the remaining 18 were divided into six groups of three, which were given doses of 20, 10, 5, 2, 1, and 0·1 mg. respectively. All but two of these guinea-pigs are alive and in good condition 730 days after inoculation No. 739 (10 mg.) and No. 740 (5 mg.) did not increase in weight to the same extent as the others. No. 739 was killed after 574 days, and small healing tubercles were found in the liver, gall-bladder, urinary bladder, and the left testis. There was no caseation. No. 740 died 672 days aft injection. Post mortem there was an acute peritonitis wi blood-stained fluid in the peritoneal cavity. There was r sign of tuberculous lesions in any organ except the left testi which had a caseous abscess of 1 cm. in diameter, and th right epididymis, which had a smaller caseous abscess, abo 0·5 cm. in diameter. *B. tuberculosis* was found in lar numbers in the smears of this caseous material. The cau of death in this animal was probably an acute perforatio of the intestine, which had no relation to the tuberculo infection. It is, however, of interest to note that caseo tuberculous lesions containing numerous tubercle baci were present in one testis and epididymis 22 months aft the intraperitoneal injection of the B C G culture 35 which was inoculated directly as received from the Instit Pasteur.

Expt. 5. B C G 359 Nov. 30th, 1928.—The secon deep subculture in bouillon of B C G 359, 9 days old, w injected into six guinea-pigs, Nos. 767 to 772. Doses of 1 1, and 0·1 mg. were given, each dose being administere subcutaneously to one animal and intraperitoneally t another. No. 768 (10 mg. intraperitoneally) was kill after 109 days; caseous lesions containing numero tubercle bacilli were present in the right testis and epididymi

795	391		0·001		
796	345		0·001		

* Killed.

B. tuberculosis was found in the culture of the heart blood taken post mortem. No. 772 (0·1 mg.i.p.) was killed, 167 days after injection, and found to be normal. The blood culture was negative. The remaining animals in this group are still alive at the time of writing—Dec. 18th, 1930.

EXPT. 6. B C G 359 Jan. 2nd, 1929.—Twenty guinea-pigs were injected intraperitoneally with the second deep subculture of B C G 359, 43 days old. As will be seen from the Table, this culture was slightly more virulent than the 9 days' old culture used in the previous experiment. No. 778 (10 mg.) died of acute generalised tuberculosis in 13 days. No. 782 (1 mg.) killed 78 days after injection, had definite caseous lesions containing tubercle bacilli in the testes, epididymes, and mesenteric glands, and a few small tubercles in the lung and liver. No. 785 (0·1 mg.) killed 137 days after injection had small healing tubercles in the liver and lung. No. 780 (10 mg.) killed at the same time, had generalised tuberculosis with caseous lesions in the lungs, liver, omentum, and right testis. No. 793 (0·001 mg.) killed 135 days after injection was normal. No. 781 (1 mg.) which died of an intercurrent infection after 328 days, showed only a few small healed lesions in the testis. The remaining animals are still alive and in good condition (Table VII.).

EXPT. 7. B C G 359 Feb. 20th, 1929.—Fifteen guinea-pigs (Nos. 849 to 863) were injected intraperitoneally with a second deep bouillon subculture of B C G 359, 92 days old. Five groups of three animals received doses of 10, 1, 0·1, 0·01, and 0·001 mg. respectively. A large proportion of the organisms in the culture were probably dead at this time, and the pathogenic properties of the culture had greatly decreased. Guinea-pigs 850 (10 mg.) and 852 (1 mg.), killed 86 days after injection, had only a few small tubercles in the liver. No. 862 (0·001 mg.), killed at the same time, was normal. No 853 (1 mg.), which died of an intercurrent infection 333 days after inoculation, showed no sign of tuberculous lesions.

EXPT. 8. B C G 359 April 3rd, 1929.—Fifteen guinea-pigs (Nos. 965 to 979) were infected intraperitoneally with the fourth deep bouillon subculture of B C G 359 43 days old. Five groups of three animals were given doses of 10, 1, 0·1, 0·01, and 0·001 mg. respectively. No. 965 (10 mg.) died 159 days after inoculation. The lungs were greatly congested and œdematous, but no macroscopic tubercles could be seen. The pleural cavity contained a great quantity of fluid. There were a few small healed tubercles in the liver. Both epididymes had caseous abscesses with numerous tubercle bacilli. Neither *B. tuberculosis* nor any other organism was found in the blood culture. No. 971 (0·1 mg.) and No. 976 (0·01 mg.), killed 44 days after infection, had a few very small tubercles in the testes, but no other tuberculous lesions. No. 968 died 605 days after infection. It was extremely emaciated. The left epididymis was the size of a large bean, and consisted of a fibrous-walled cyst full of caseous material in which numerous clumps of acid-fast tubercle bacilli were found. The wall of the cyst was slightly calcified in places. There was no normal tissue left. No other definitely tuberculous lesion was found. On the peritoneal surface of the small intestine there was a greyish-white thickened area about one centimetre long but no tubercle bacilli were found in it.

Discussion.

From these experiments it is apparent that under certain comparatively simple cultural conditions, B C G may at times develop a relatively high degree of virulence for laboratory animals. This phenomenon of mutation is still under investigation, and it is impossible at present to say exactly what factors in the medium or in the conditions of culture are responsible for bringing about this change. It is possible that the cultural methods employed favoured the development of organisms analogous to the "S" type isolated by Petroff, and partially suppressed the growth of the "R" type.

The two B C G cultures, B C G (I) and B C G 359, behaved very differently with regard to the development of virulence when grown under apparently similar conditions. In the case of B C G (I), all of the experimental animals infected with the deep culture, both rabbits and guinea-pigs, developed widespread progressive tuberculous lesions, which showed no tendency to heal. Guinea-pigs infected with the organs of these animals, or cultures isolated from them also developed progressive tuberculous lesions. Guinea-pig 727, injected with a blood culture from No. 521, failed to develop generalised tuberculosis, but the number of organisms in the culture injected was very small. The blood culture from No. 727, however, contained *B. tuberculosis*. The three guinea-pigs injected with blood cultures from other guinea-pigs in the same series all developed generalised tuberculosis.

In the case of B C G 359, only one of 20 guinea-pigs inoculated with the *original culture* as received from the Pasteur Institute had localised caseous tuberculous lesions in one testis and one epididymis when it died 22 months after inoculation. Another, killed 15 months after injection, had several healing lesions, but no sign of progressive tuberculosis. The second deep bouillon subculture of this strain was tested at three different stages, when 9, 43, and 92 days old. One of six guinea-pigs injected with the 9 days' old culture had caseous lesions in one testis and epididmyis when killed 169 days after inoculation. Another was normal. The 43 days' old culture proved to be slightly more virulent. Of 20 guinea-pigs, 1 died of acute generalised tuberculosis in 13 days; and 2 killed 78 and 137 days respectively after inoculation both had caseous lesions. None of the 15 guinea-pigs injected with the 92 days' old culture had developed generalised tuberculosis. Two, killed 86 days after infection, showed only a few very small tubercles in the liver, and a third, which had only 0·001 mg., was normal. The fourth deep subculture, tested when 43 days old, produced caseous lesions in the epididymes of two guinea-pigs, which died in 159 and 605 days respectively. Two other guinea-pigs, killed after 44 days, had a few small tubercles in the testes.

Before final conclusions as to the pathogenicity of tubercle bacilli can be drawn, it is very important that the animals should be kept under observation for a period, not of months but of years. We are, therefore, in full agreement with Petroff and with Watson, that in the great majority of experiments on the pathogenicity of B C G, the animals have been killed too soon after inoculation. A prolonged latent stage in an apparently benign infection cannot be taken as a criterion of the final outcome. Accordingly, all our surviving animals infected with B C G 359 are being kept, and will be reported on later.

Whether the marked difference in virulence of the deep cultures is inherent in the two strains of B C G, or is due to the influence of unknown factors beyond our control during the growth in deep cultures is impossible to say. In view of the experiments of others, it is likely that part, at least, of the difference is inherent in the strain. Thus, Petroff and Steenken (1930) found that "culture B C G 359 (which Petroff obtained in the fall of 1928 from the Pasteur Institute) was more difficult to dissociate than the three cultures which had previously been obtained." Watson (1930), referring to his pathogenicity tests, reports that "more positive results have been obtained with B C G Strain 80 (1924) than with Strain 17 (1925), while only one positive result has so far been obtained with Strain 346 (1927)."

It seems probable, as suggested by both Petroff and Watson, that continuous propagation of the culture on bile media has gradually further reduced its virulence since it was first generally used for immunisation.

Summary.

1. The pathogenic properties of two strains of B C G have been investigated.

2. Deep bouillon subcultures of B C G (I) produced generalised tuberculosis in all of 28 guinea-pigs which

were inoculated intraperitoneally with doses of from 0·1 to 20 mg., and produced severe progressive tuberculous lesions in all of 12 rabbits inoculated intravenously with doses of from 5 to 50 mg. Twenty-two of 23 guinea-pigs infected either directly with tuberculous material from these animals, or with cultures from the tuberculous material, developed generalised tuberculosis. *B. tuberculosis* was found in cultures from the heart blood of all of the 28 guinea-pigs injected directly with deep cultures of B C G (I), and in 19 of the 23 guinea-pigs infected with pathological material or cultures obtained from the animals originally infected with this culture.

3. The pathogenicity of B C G 359 was tested on guinea-pigs. One of 20 guinea-pigs injected with the culture as received from the Pasteur Institute died from an unknown cause 672 days after an intraperitoneal dose of 5 mg., having caseous tuberculous lesions without signs of healing, in the right testis and the left epididymis. Deep bouillon subcultures of this strain were tested on 56 guinea-pigs, 12 of them receiving doses of 10 mg. intraperitoneally; of these 12, 3 which were killed and 2 which died had definite progressive tuberculous lesions, and 4 of the 5 had caseous abscesses in the testes or epididymes.

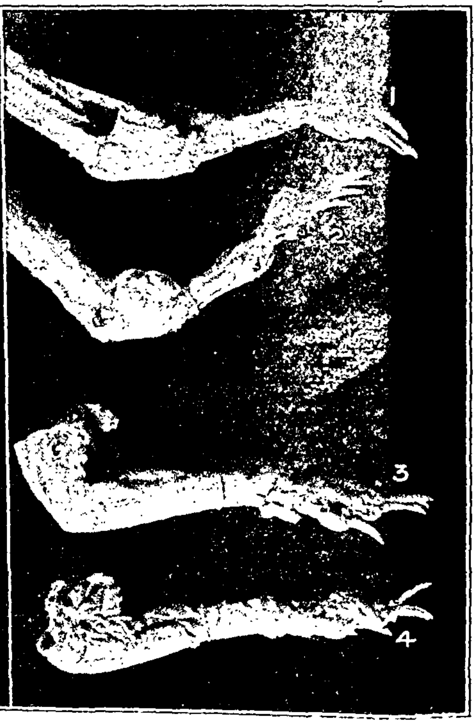
FIG. IV.



Same as Fig. III. Lateral view.

We are indebted to Dr. Calmette of the Pasteur Institute for kindly supplying the culture of B C G 359 to the Medical Research Council, who were good enough to forward it to us; and to Captain S. R. Douglas, F.R.S., for the culture B C G (I). We especially wish to thank Dr. R. H. Sankey for taking the X ray photographs, and Dr. A. Stanley Griffith, who has given us his experienced opinion on two cultures submitted to him. Our thanks are due to Mr. Jesse Wheal and Mr. J. L. Nappin for their painstaking care of the animals which is so necessary in these prolonged experiments. One of us (R L V.) is greatly indebted to the Medical Research Council for a part-time grant.

Report on Two Cultures

BY DR. A. STANLEY GRIFFITH.

Two cultures taken from rabbit 201 and guinea-pig 526, marked TB 201 and TB 526 respectively, were sent to Dr. Stanley Griffith, who had kindly undertaken to type them for us. He was entirely unaware of the type and origin of the cultures. TB 201 was isolated from the knee-joint of rabbit 201 (expt. 2), and TB 526 was isolated from the testis of guinea-pig 526 (expt. 3). As well as studying the cultural characters of these two strains, Dr. Griffith made the following animal experiments.

TB 201.

Guinea-pig 5268 was injected with about 10 mg. subcutaneously. It weighed 390 g. on the day of injection, and 320 g. when killed 37 days later. The post-mortem findings were: Large ulcer. Inguinal glands, caseous and softened; iliac, portal, and bronchial glands caseous in cortices. Spleen enlarged, with necrotic patches in the margin. Liver mottled with yellow foci. Lungs contained tubercles.

Guinea-pig 5269, injected subcutaneously with about 1 mg. It weighed 400 g. on the day of injection, and also 400 g. when killed 82 days later, being paralysed. Post mortem, there was a chronic generalised tuberculosis, the lesions showing little caseation.

Rabbit 3450 was injected subcutaneously with 10 mg. of a culture isolated from guinea-pig 5268. It weighed 1820 g. on the day of injection, and 2300 g. when killed 146 days later. The post-mortem findings were: Softened caseous lesion. Scapular glands, caseous and softened. Lungs contained a moderate number of grey caseating nodules, 2 to 3 mm. in diameter, mainly dorsal. No tuberculosis elsewhere.

TB 526.

Guinea-pig 5270, injected subcutaneously with about 3 mg., weighed 420 g. on the day of injection, and 350 g. when it died 86 days later. The post-mortem finding was typical severe generalised tuberculosis.

Guinea-pig 5271, injected subcutaneously with about 10 mg., weighed 280 g. when injected, and 250 g. when it died 40 days later. The post-mortem examination showed a generalised tuberculosis. The liver and spleen were closely beset with submiliary grey-white tubercles.

Rabbit 3465 was injected subcutaneously with 20 mg. of a culture isolated from guinea-pig 5271. It weighed 1500 g. when injected, and 2570 g. when it was killed 226 days later. Post mortem, there was only a softened local lesion.

Rabbit 3535, inoculated intravenously with 0·01 mg. of culture TB 526, weighed 1550 g. when inoculated, and 1800 g. when killed 69 days later. Post mortem, in the lung there were some grey, caseating superficial and marginal patches, as well as discrete caseating tubercles, not numerous;

FIG. VI. (Expt. 2, Rabbit 201).—Radiogram of hind leg (2), lateral and dorsal aspects. Bone destruction less advanced than in (1).

FIG. VII. (Expt. 2, Rabbit 201).—Radiogram of fore leg (3), lateral and dorsal aspects, showing very early bone changes.

FIG. VIII. (Expt. 2, Rabbit 201).—Radiogram of fore leg (4), lateral and dorsal aspects, showing very early bone changes.

FIG. IX. (Expt. 3).—Lungs of guinea-pigs, showing extensive tuberculous lesions.

PROF. DREYER AND MR. VOLLUM:
EXPERIMENTS WITH B C G.

the tracheal glands contained caseating tubercles, and there were three or four small tubercles in the kidneys.

In his report, Dr. Griffith says: "The cultures are 'mammalian,' but do not conform exactly either to the human or to the bovine type. Both strains have grown with rather more luxuriance on egg and glycerin media than any strain obtained from bovine tuberculous lesions though not equal to the eugonic human type of tubercle bacillus or to B C G. Culturally, they resemble bovine strains which have been modified by cultivation on media containing glycerin. The results of the virulence tests are inconclusive, owing to the small number of animals used. Both strains were virulent for the guinea-pig, producing typical general tuberculosis, while for the rabbit they were of relatively low virulence, the pathogenic effects not exceeding in severity those which are sometimes produced by standard human bacilli."

ELECTROCARDIOGRAPHIC CHANGES DURING BRIEF ATTACKS OF ANGINA PECTORIS.

THEIR BEARING ON THE ORIGIN OF ANGINAL PAIN.

BY JOHN PARKINSON, M.D., F.R.C.P. LOND.,

PHYSICIAN (WITH CHARGE OF OUT-PATIENTS) AND PHYSICIAN IN CHARGE OF THE CARDIOGRAPHIC DEPARTMENT, LONDON HOSPITAL; PHYSICIAN TO THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART;

AND

D. EVAN BEDFORD, M.D., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE MIDDLESEX HOSPITAL.

THE electrocardiogram of patients subject to angina pectoris is commonly abnormal, and provides evidence of permanent disease of the heart muscle. Pathological observation has proved that such disease is most often an ischæmic fibrosis of the myocardium due to obliterative arterio-sclerotic changes in the coronary field. During the last decade there has been separated from the brief anginal attacks induced by effort the prolonged anginal seizures caused by thrombosis of a coronary artery and consequent localised infarction of the heart. During and after these anginal seizures due to cardiac infarction the ventricular deflections of the electrocardiogram are often profoundly modified, and serial records show a characteristic sequence of changes which represent a progression of pathological events in the heart.[7] A vast number of such electrocardiograms has been taken and reported in cases of anginal pain due to cardiac infarction.

Remarkably few examples are on record of electrocardiograms taken during ordinary brief paroxysms of angina pectoris. Clerc[3] figures inversion of the T waves during an anginal attack and a return to normal after the attack, though it is not quite clear from the text whether the attack was coronary thrombosis or an ordinary paroxysm of angina pectoris. Arrilaga[1] says that during pain he has observed bundle-branch block which disappeared when the pain ceased. Bousfield[2] has reported a case of syphilitic aortitis in which, during a short anginal attack, a right bundle-branch block was recorded which disappeared shortly afterwards with cessation of the pain. The electrocardiogram after the attack showed such deep inversion of the T waves in leads II. and III. as would nowadays suggest cardiac infarction, but the after-history of the case is not given. Gallavardin and Rougier[5] have published a long electrocardiogram taken during an anginal attack accompanied by syncope and a fall of blood pressure with a pulse which became impalpable at the wrist. In parts of this curve there is obvious depression of the R–T segment of the ventricular complexes, yet its significance is doubtful viewing the complexity of the case. The most important observations are those of Feil and Siegel,[4] who published electrocardiograms taken during and after short anginal attacks in four cases where cardiac infarction could be excluded. In three they recorded a definite depression of the R–T segment of the ventricular complex in leads I. and II. during the pain, and a return to normal after the pain had ceased.

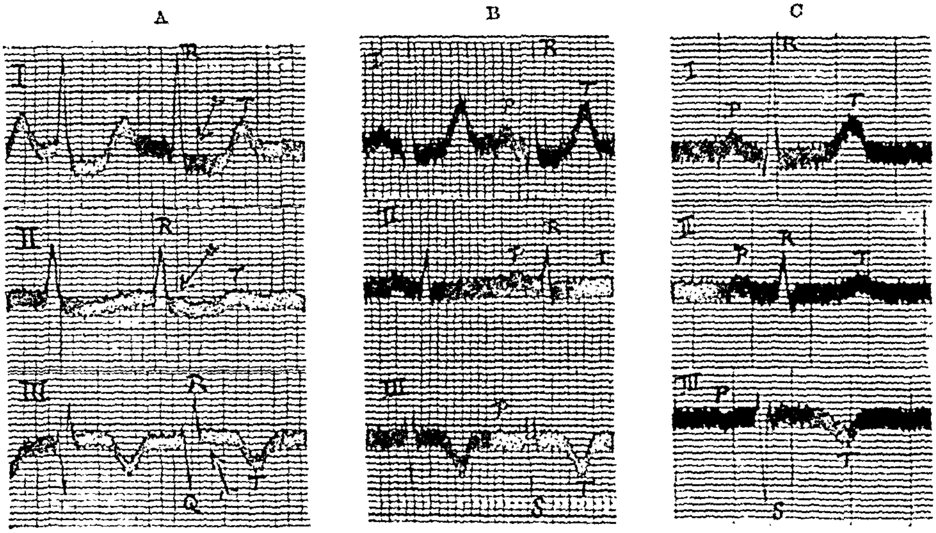
Opportunities of taking electrocardiograms during transient anginal attacks arise but rarely and by chance, and it seems desirable that all such records should be reported whether giving positive or negative evidence of change. Thus, in the course of time, a sufficient number will be available from which valuable conclusions may be drawn. We have been fortunate enough to see five patients from whom electrocardiograms were obtained during and after short paroxysms of anginal pain. These did show that the ventricular deflections were modified during the paroxysm of pain and that the modifications disappeared with the pain. In none of these cases was there any question of coronary thrombosis at the time the records were taken, though one patient had probably had coronary thrombosis three months previously.

Five Case Records.

CASE 1.—Female aged 59. For some years she had been easily breathless when, in 1923, she began to feel pain at the upper half of the sternum, spreading down both arms to the wrists, always induced by exertion and eased by rest. In some of the attacks she noticed palpitation which stopped suddenly as the pain eased. When seen in July, 1924, the heart was not enlarged (X ray). Heart sounds normal. Blood pressure, 140/95 mm. Wassermann reaction negative. During her first visit she was observed in a typical severe anginal attack, and at the height of the pain the pulse, first noted regular and of moderate rate, became completely irregular and frequent. An electrocardiogram taken while the pain was still present showed auricular fibrillation. Fifteen minutes later, after all pain had ceased, a second record showed normal rhythm. In spite of prolonged rest anginal attacks recurred over a year and in July, 1925, cervical sympathectomy was performed. Some improvement followed; but in June, 1928, she was still subject to anginal pain on exertion. The heart was now enlarged to the left and the aorta somewhat widened (X ray).

The electrocardiograms are reproduced in Fig. 1. The first curve (A) taken during an attack of anginal pain, shows auricular fibrillation and also depression of the R–T segment of the ventricular complexes in leads I. and II.; in lead III. the initial ventricular complex is diphasic, consisting of a downward deflection Q followed by an upward one, R. In the second curve (B) taken 15 minutes later, normal rhythm is present and the R–T segment has become iso-electric; in lead III. there is a single downward deflection of the initial ventricular complex S. In the third curve (C) taken two months later in the absence of pain, T is upright in lead II., and R–T is iso-electric.

FIG. 1 (Case 1).



During anginal attack. Fifteen minutes after attack. Two months later.

(A) Auricular fibrillation during attack, R–T deviation in all leads (arrows); (B) Normal rhythm, R–T deviation has disappeared, T flat in lead II.; (C) T upright in lead II.

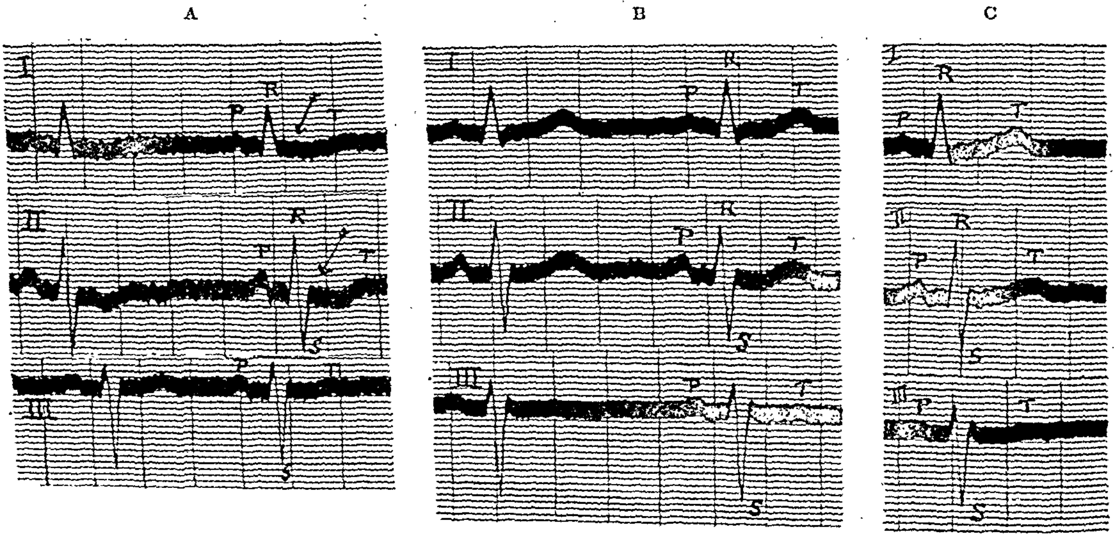
CASE 2.—Male aged 65. First seen in February, 1930. For a month he had been liable to pain in both wrists at times, and for 10 days he had had attacks of burning pain at the upper half of the sternum, lasting a few minutes. On examination, the heart was found to be moderately enlarged and the aorta slightly widened as if by atheroma (X ray). At the apex the sounds were distant, and the aortic second sound was accentuated. The arteries were slightly thickened; the blood pressure was 185 mm. systolic. A typical anginal attack was witnessed, and while the pain was still present an electrocardiogram was obtained. A second record was taken 40 minutes later, after pain had entirely ceased, and a third was taken two months later, when he was out of pain though still subject to it on exertion.

The electrocardiograms are reproduced in Fig. 2. There is distinct depression of the R–T segment and of the T wave in leads I. and II. in the attack (Fig. 2, A) compared with subsequent records (Fig. 2, B and C), while in lead III. T is upright in the attack and flat in later curves.

CASE 3.—Male, aged 70, was first seen in August, 1930. There was a history of syphilis at the age of 23. Two years previously he had first felt pain at the lower part of the sternum while cycling uphill. A few months later he began to suffer from frequent anginal attacks always induced by exertion; the pain was sternal and radiated to the left arm. On examination, signs of aortic incompetence were found. The heart was slightly enlarged to the left and the aorta showed the general dilatation typical of syphilitic aortitis (X ray). Blood pressure, 120/65 mm. Wassermann reaction positive. During a short attack of anginal pain an electrocardiogram was obtained, and another 10 minutes later, when pain had gone.

These electrocardiograms are reproduced in Fig. 3. During the pain (Fig. 3, A) there is a depression of R–T in all leads notably in lead II., and the T wave in lead III. is smaller amplitude than after the attack. In the second curve (Fig. 3, B) after all pain

FIG. 2 (Case 2).



During anginal attack. Forty minutes after attack. Two months later.

(A) R–T depression and flat T waves in leads I. and II.; (B) R–T depression disappeared, upright T in leads I. and II.; (C) No change.

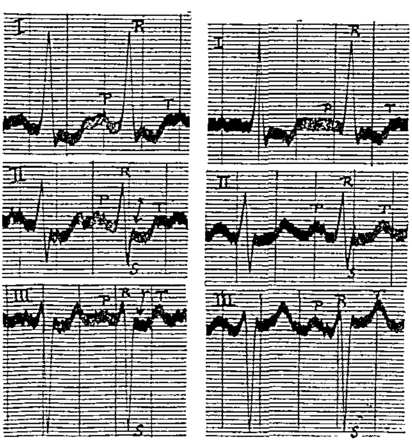
had ceased, the R–T segment has returned to iso-electric level in leads II. and III.

CASE 4.*—Male, aged 60, first seen in July, 1930. For ten years he had been getting increasingly breathless, and in December, 1929, he first began to feel pain in the chest on exertion which forced him to stand still, and which eased rapidly with rest. The pain started near the right nipple and spread to the lower end of the sternum and across the chest. The attacks became more frequent and more easily provoked and, on June 7th, 1930, he had a severe anginal seizure lasting four hours, in which the pain spread down both arms to the fingers. This was followed by recurrent severe and prolonged attacks of pain. On July 24th, 1930, he was admitted to hospital, as it was thought that his severe and prolonged attacks of pain were due to cardiac infarction.

On examination, pulse regular, rate 70. Arteries were not thickened; blood pressure, 120/80 mm. Apex-beat in nipple line; heart sounds distant, no murmurs. No signs of heart failure. X ray examination, heart normal in size, aorta very slightly widened. Electrocardiogram, normal rhythm, T waves flattened in all leads, and very slight R–T deviation in opposite directions in leads I. and III.

During a stay of seven weeks in hospital this patient had a number of short anginal attacks usually induced by emotion or slight exertion and rapidly relieved by amyl nitrite. Shortly before his discharge from hospital, when he had greatly improved, he had a mild anginal attack lasting a few minutes while in the cardiographic department, during which an electrocardiogram (Fig. 4, A) was taken. Another record (Fig. 4, B) was obtained ten minutes later, after all pain had ceased. The first record, taken during the pain, showed obvious inversion of the T wave in leads I. and II., with deviation of R–T below the zero level in lead I. and above it in lead III. In the second curve, after pain had ceased, T was flattened in lead I. and upright in lead II., and R–T deviation had almost disappeared. An hour later he had another milder anginal attack, during which the third record (Fig. 4, C) was obtained, and five minutes later, after all pain had ceased, the fourth record (Fig. 4, D) was taken. These last two curves exhibit the same changes, though of slighter degree, during the pain as were recorded in the previous attack—namely, inversion of T in lead I. and R–T deviation in leads I. and III. Another electrocardiogram taken five days later, when he was free from pain, was identical with the other records between attacks. The two anginal attacks in which these records were obtained were not at all severe, lasted only a few minutes, and occurred three months after his symptoms of cardiac infarction, at the time of his discharge from hospital and when he had greatly improved. The changes in the electrocardiogram during anginal pain were transitory, for within a few minutes the curve had returned to its normal form—i.e., identical with records taken

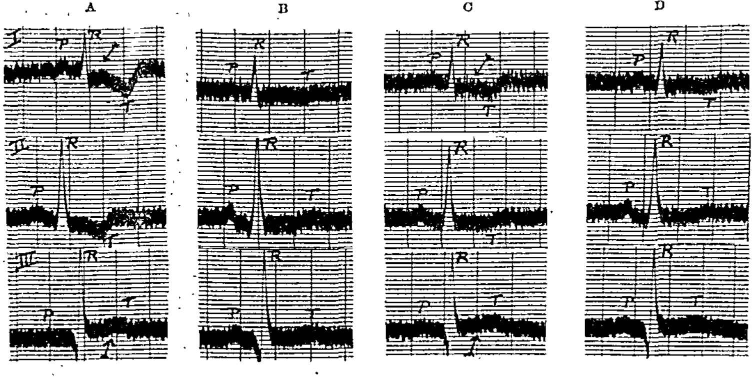
FIG. 3 (Case 3).



During anginal attack. Ten minutes after attack.

(A) R–T depression in all leads, marked in lead II.; (B) R–T iso-electric in leads II. and III.

FIG. 4 (Case 4).



During anginal attack. Ten minutes after attack. During milder anginal attack. Five minutes after attack.

(A) R–T deviation in leads I. and III., and inversion of T in leads I. and II.; (B) T flat in lead I., positive in lead II., R–T deviation diminished; (C) Reappearance of R–T deviation and of T wave inversion in lead I.; (D) Return to form seen in (B).

---

* The electrocardiograms in this case were all taken in the Cardiographic Department, London Hospital, by Dr. Harold Cookson, and we are much indebted to him for placing them at our disposal.

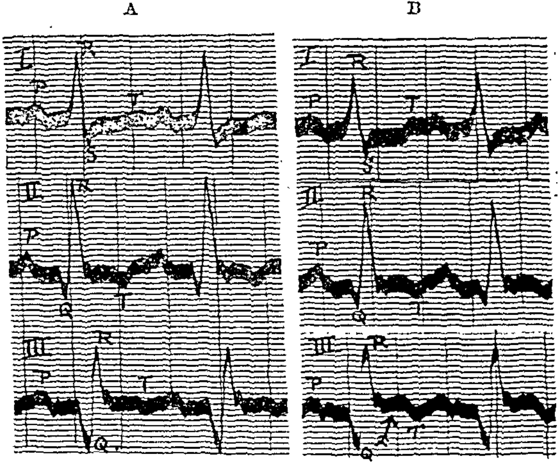
before and after the day on which these two particular attacks occurred.

CASE 5.—Male, aged 53, seen in September, 1930. For two years he had suffered from a burning pain above both nipples on exertion, lasting a few minutes, and during the last year the pain had radiated down both arms in the attacks. Since March, 1930, he had had several nocturnal anginal attacks each lasting about 15 minutes. On examination, the arteries were slightly thickened; blood pressure 160/110 mm. At the apex, the sounds were distant, and the aortic second sound was accentuated. X ray examination heart considerably enlarged to the left, aorta slightly widened. No signs of congestive heart failure. Wassermann reaction negative.

Electrocardiogram (Fig. 5, A) showed abnormal widened QRS waves in all leads, and inversion of T in leads II. and III. The curve probably represents a partial bundle-branch defect.

While dressing, pain in the chest started but passed off after amyl nitrite. Shortly afterwards pain recurred becoming fairly severe, sweat appearing on the forehead. While this pain was present a second electrocardiogram (Fig. 5, B) was taken, and a third after pain had ceased. When compared with curve A, taken before the attack, curve B, taken during the pain, shows the following slight changes: in lead III. there is definite slight elevation of R-T and a sharply pointed negative T has appeared, while the notch at the summit of R is widened. In lead I. there is a slighter depression of R-T, and T appears diphasic compared to the first curve. Though these changes are slight in degree, they are definite and similar in nature to those occurring in the previous cases.

FIG. 5 (Case 5).



Before anginal attack. During anginal attack.

(A) Abnormal widened QRS in all leads, T negative in lead II.; (B) R-T deviation in leads I. and III., notably in lead III., and also widening of summit of R in lead III.

DISCUSSION.

In all these five patients electrocardiograms taken during short anginal paroxysms showed definite and transitory changes in the ventricular deflections. There was a depression of R-T and a diminution in the amplitude or inversion of the T waves in one or more leads, changes closely resembling though not so pronounced as those which follow cardiac infarction in the early stages. It is surely significant that both transient anginal pain and cardiac infarction can affect the electrocardiogram in a similar manner; and it seems reasonable to infer that the mechanism underlying this electrocardiographic change is essentially the same in both cases—an ischæmia of a part of the cardiac muscle. We do not suppose that the electrocardiogram is always modified during short anginal attacks, but our evidence confirms that of Feil and Siegel that it is modified in a proportion of cases. The fact is of considerable significance in relation to the pathogenesis of anginal pain. Even in undoubted cardiac infarction, the electrocardiogram sometimes fails to give evidence of it. If, then, as we believe, paroxysmal anginal pain is the manifestation of a similar but transient ischæmia, we should expect its electrocardiograhic changes to be slighter in degree and less constant than in cardiac infarction.

Pathogenesis of Anginal Pain.

Of the many theories which have been advanced to explain the causation of anginal pain since Heberden first described it, only two have stood the test of time and gained any degree of general acceptance—namely, the coronary theory which should include myocardial ischæmia and the aortic theory. Since Jenner's time, attention has been riveted on the coronary arteries, and a vast amount of solid pathological evidence has been accumulated in support of Jenner's theory, notably by Huchard. In spite of this, the aortic theory appeared to be gaining favour in what might be called the pre-coronary-thrombosis era, thanks to the eloquence and authority of its sponsors, especially Allbutt. During the last fifteen years our knowledge of the anatomy, physiology, and pathology of the coronary circulation has been greatly extended, and the study of coronary thrombosis has revealed many new facts of importance in relation to angina. When the pathogenesis of anginal pain is reconsidered in the light of this additional knowledge, attention must inevitably centre once more on the coronary arteries; and the claim that they are the source of anginal pain seems to-day wellnigh incontestable. Before the theory of the aortic origin of angina can again be supported, more conclusive evidence than that at present available is required, and we do not believe that it will now bear critical examination.

The crux of the problem has always been this—that a paroxysmal pain cannot be explained simply in terms of morbid anatomy, for the anatomical lesion is there before the pain begins, during the pain, and after the pain has subsided. In order to correlate a transient disturbance of function with a permanent structural change, an additional factor is required—for example, coronary spasm, claudication or cramp of the heart, or aortic distension—and this factor can neither be confirmed nor refuted by evidence found at necropsy. Now in coronary thrombosis, coincident with the pain something has happened in the heart which was not present before the onset of pain, something, moreover, which can be demonstrated at necropsy. In other words, coronary thrombosis provides the proof that anginal pain can and often does have a coronary *origin*. Where a prolonged anginal seizure from cardiac infarction arises in a patient previously subject to anginal pain on exertion, we can scarcely avoid the assumption that the *paroxysmal pain had as its basis* the coronary atheroma of which thrombosis was a final *complication*. We have a parallel in cerebral arteriosclerosis, where transient disturbances of function ("cerebral angiospasm") not infrequently precede cerebral thrombosis, or in peripheral arterio-sclerosis where intermittent claudication or nocturnal cramps may precede gangrene of the limb. As Gallavardin has remarked, not every case of arterio-sclerotic gangrene has suffered from claudication any more than every case of cardiac infarction has suffered from previous angina.

The acceptance of the coronary theory of angina will have a salutary effect on medical thought and practice, but it is only the beginning of the problem *of anginal pain and not the end. Does the pain* arise in the artery itself or in the ischæmic myocardium? The theory of myocardial ischæmia, first put forward by Allan Burns, has recently been amplified by Keefer and Resnik[6] under the name of myocardial anoxæmia, and they show that it is not difficult to explain, in terms of coronary insufficiency, the occurrence of anginal pain in aortic incompetence, severe anæmia, and other conditions under which it is also encountered clinically. Indeed it has now become more difficult to explain the absence of anginal pain than its presence. We do not know why, in certain cases, cardiac infarction should remain quite painless, and further careful study of such exceptions is required. The coronary theory need not be an exclusive one, nor does its acceptance involve rejecting entirely the possibility of anginal pain also originating in the aorta.

In support of the coronary theory we have presented evidence that ordinary attacks of angina pectoris arise in the myocardium, and that they differ only in degree from the prolonged anginal seizures due to cardiac infarction. In one we have a functional ischæmia, in the other an organic. It is difficult to conceive a functional ischæmia arising otherwise than from coronary spasm. Without pretending to discuss other evidence for and against coronary spasm, we would suggest that, if it does occur, the appropriate site for it is in the arterioles. If a main coronary branch be narrowed by atheroma, this may well predispose to spasm of the arterioles which spring from it beyond the obstruction, for there is evidence that such is the mechanism by which the pain of intermittent claudication is produced in the limbs.

POST-INFLUENZAL ACUTE PARENCHYMATOUS KERATITIS.

BY J. H. DOGGART, M.B. CAMB., F.R.C.S. ENG.,
RESEARCH SCHOLAR, MOORFIELDS EYE HOSPITAL.

NEARLY all the components of the visual apparatus are susceptible to damage from the toxin or toxins of influenza. In the number and variety of its ocular manifestations influenza probably surpasses all other acute infectious diseases. The commonest complication is an acute conjunctivitis, seldom severe, accompanying the respiratory form of the disease, and induced by upward spread of the infection from the nasal mucous membrane along the nasolacrymal duct. Most of the other complications might be more *accurately described as sequels, since they tend to* arise at the end of an attack of influenza or during the convalescent stage. Well known examples of these sequels are herpes febrilis of the cornea, iridocyclitis, optic neuritis affecting the nerve-head or *the retrobulbar portion of the nerve*, panophthalmitis, extrinsic or intrinsic ocular palsies, dacryo-adenitis, and orbital abscess. In the past two years I have made observations on eight patients who, during the first month of convalescence from influenza, developed acute parenchymatous keratitis complicated by iridocyclitis. All of them were in the fourth or fifth decade of life, and neither sex predominated. One of the women had suffered from attacks of corneal ulceration after measles in childhood, but none of the others gave any history of previous inflammatory trouble of the eyes. The attack was unilateral and painful in every case.

Clinical Description.

Within a few weeks of apparent recovery from a bout of influenza one eye begins to suffer from irritability and photophobia. Although pain is a prominent feature, its full development is often delayed for two or three days, so that an insidious onset results. On examination of the affected eye, conjunctival and ciliary injection are obvious. In the central region of the cornea is a deep greyish haze, behind which can be seen a few localised keratic precipitates. The epithelial surface lacks its normal lustre, and frequently shows minute erosions, some of which may coalesce to form a corneal ulcer. One or more nodules of episcleritis near the limbus can often be seen. Superficial vessels are apt to encroach on the peripheral region of the cornea around part of its circumference. Evidence of iritis is provided by engorgement of the vessels near the surface of the iris, together with discoloration and impairment of its pattern. The pupil responds well to the action of atropine in the early stages of the affection. Fragments of pigment torn away during the process of mydriasis will be found adhering to the anterior capsule of the lens. The fundi are normal.

With the aid of the slit-lamp, the central corneal infiltration is seen to consist of a multitude of grey dots situated in the middle and superficial layers of the substantia propria. Linear streaks or "false folds" are found in the deepest layers of the corneal substance, and there is well-marked bedewing of Descemet's endothelium. In addition to the large central keratic precipitates already seen with a loupe, there are usually some smaller precipitates on the back of the rest of the cornea, especially in its lower part. The appearance of the epithelium is variable, but some degree of roughening and bedewing can always be detected, whether or not the surface has become actually eroded. Numerous particles can be seen floating in the anterior chamber.

The above-described condition responds well to treatment by means of rest, heat, irrigation with weak antiseptic lotion, and the application of atropine ointment. Nevertheless, the patient should remain under observation for some weeks after the eye has settled down, because recurrence of iridocyclitis or corneal ulceration was noted in several cases. A convalescent holiday is the best protection against such relapses. Transparency of the cornea is not completely restored, but the eventual degree of opacity is not great.

It is necessary to emphasise the unilaterality of this condition, because the commoner type of post-influenzal iridocyclitis is bilateral, and presents the *following points of distinction: (a) It is not complicated* by infiltration of the corneal substance. (b) Pain is not a prominent feature. (c) It has no tendency to recur.

ILLUSTRATIVE CASES.

CASE 1.—A man, aged 47, developed typical respiratory influenza in March, 1930. There was an abrupt onset, accompanied by severe headache, acute coryza, and a rise in temperature lasting four days. Eight days after the beginning of the attack he was able to get out of bed, but had not yet fully recovered his strength. A few days later the left eye began to suffer slight pain and irritability, which steadily grew worse until he attended Moorfields as an out-patient three weeks after the onset of influenza.

On examination the right eye was normal. The left eye showed conjunctival and ciliary injection; a small ulcer on the superotemporal quadrant of the cornea near the limbus; *localised central corneal infiltration and keratic* precipitates; engorgement of the iris vessels, and one posterior synechia below. After initial curettage and carbolisation of the ulcer, treatment consisted of hot applications and atropine instillation. Pigmented fragments torn away from the *posterior surface of the iris* were observed adhering to the anterior lens capsule after the pupil became *dilated*.

Four days later the ulcer had healed. The corneal infiltration could be resolved into numerous grey dots situated in the anterior two-thirds of the substantia propria. Several striæ were detected in the deepest layers of the substantia, and endothelial bedewing was present over the whole posterior surface. Many circulating particles were visible in the aqueous humour. One month later a fresh corneal ulcer appeared *at the site of the previous one, but* healed within four days. After a further three weeks, early in June, there occurred a mild relapsing iritis which subsided after three days. The patient then went away for a fortnight's convalescent holiday, since when he has had no further trouble. His fellow eye never showed any sign of involvement. The fundi were normal.

The patient had never suffered from syphilis, and the lesions of the left cornea differed from ordinary syphilitic interstitial keratitis in the following main respects: (*a*) There was no infiltration or vascularisation of the deepest layers of the substantia propria. The only new-formed vessels were a few superficial ones in the neighbourhood of the ulcer. (*b*) The infiltration was localised to the axial portion of the cornea. (*c*) Part of the corneal surface underwent ulceration—a process that hardly ever occurs in syphilitic interstitial keratitis.

CASE 2.—A woman, aged 58, was treated eight years ago for keratitis and iridocyclitis of the right eye arising one week after recovery from a sharp febrile attack of respiratory influenza. Examination this year revealed shrunken pigmented remains of keratic precipitates in the central portion of the right cornea. In the anterior and middle layers of the substantia propria the arrangement of the lamellæ had undergone distortion. Striæ were present in the posterior layers. The total thickness of this cornea in its central region was increased 20 per cent. No vascular remains were found. The left eye and both fundi were normal. There was no evidence of syphilis. The continued freedom of the fellow eye now that eight years have elapsed since the original attack provides a good example of the unilaterality of this complication.

The above cases were under the care of Sir John Parsons, to whom I am indebted for permission to publish them.

Comment.

Similar corneal involvement in malaria and mumps.—Malaria has long been known to share with influenza the capacity to produce herpetic keratitis, followed by dendritic ulceration of the cornea. It is interesting to note that these two diseases can both attack also the substantia propria, for Maxwell[1] has reported central interstitial or discoid keratitis as an occasional complication of malaria. Lunsgaard[2] has recorded two cases of acute infiltration of the superficial and middle layers of the corneal substance arising during the second week of an attack of mumps. He remarks on the associated roughening of the epithelium, but found no involvement of the iris.

Post-influenzal acute parenchymatous keratitis without iridocyclitis.—In the literature concerning the ocular manifestations of influenza I have not so far found any reference to acute parenchymatous keratitis accompanied by a definite iridocyclitis. Pflüger[3] saw two cases of central infiltration of the corneal substance, both of them unilateral, following influenza in healthy males who provided no evidence of trauma, syphilis, or previous eye trouble. He makes no mention, however, of any accompanying iridocyclitis. Cosse[4] recognised parenchymatous keratitis as a possible complication. Rampoldi[5] saw corneal infiltration several times among a long series of cases occurring during an influenza epidemic, and thrice observed relapsing parenchymatous keratitis of the syphilitic variety. It seems appropriate here to mention that none of the cases which I examined showed any of that deep vascularisation which would make one suspect a syphilitic origin.

Neuropathic factor.—Perhaps neuropathic disturbances play their part in producing this affection of the cornea. Influenza can do damage, either directly or through the spread of inflammation from adjacent meninges, to the Gasserian ganglion or to the first division of the fifth cranial nerve. Monbrun[6] saw many cases of neuroparalytic keratitis during the 1918–19 epidemic. These were characterised by complete anæsthesia of the cornea. Certainly there was sooner or later a disturbance of corneal sensation in most of the cases that I examined, but no conclusion could be legitimately drawn therefrom. When the cornea is afflicted with ulceration of its surface or acute infiltration of its deeper layers, then inferences derived from its degree of sensibility are apt to be fallacious.

Summary.

The main features of post-influenzal acute parenchymatous keratitis are briefly these: (1) it occurs in the stage of convalescence; (2) it is unilateral; (3) iridocyclitis accompanies it, and is prone to relapse; and (4) the anterior and middle layers of the substantia propria are chiefly involved, but epithelial erosion may also occur.

THE ACTION OF LIVER PREPARATIONS IN DIABETES.

BY P. C. BRETT, M.D. LOND.,

W. A. BROOM, B.SC., A.I.C.,

AND

F. O. HOWITT, B.SC., A.I.C.

(*From the Research Department, Boots Pure Drug Co., Ltd., Nottingham.*)

Blotner and Murphy's observations that the oral administration of liver[1] or of a particular liver concentrate[2] causes a lowering of the blood-sugar appeared to be of such practical importance that attempts have naturally been made to repeat them. Thus, de Pencier, Soskin, and Best[3] obtained *no* evidence that the ingestion of raw liver lowers the blood-sugar of normal dogs or that a lowering of blood-sugar or sugar excretion occurs in depancreatised dogs. This latter finding is of importance, since Macleod[4] considers that in the laboratory the depancreatised animal is necessarily the final court of appeal when judging the merits of a substitute for insulin. Murlin, Pierce, and Gregg[5] expressed the belief that the effect of liver feeding in diabetes as reported by Blotner and Murphy is due to the insulin which the liver contains, a suggestion which the work of de Pencier et al. failed to substantiate. Bowen[6] found no evidence of a hypoglycæmic action of liver in a patient suffering from combined diabetes and pernicious anæmia, and Lawrence[7] has now reported that he was unable to detect any lowering of the blood-sugar of a diabetic after the oral administration of liver extract prepared as described by Blotner and Murphy in doses equivalent to 2 lb. of liver. According to Lombardi,[8] however, liver pulp appears to contain a hypoglycæmic substance.

We therefore think it may be of interest to record that we have carried out Blotner and Murphy's directions for the preparation of this special extract of liver on several occasions, and have consistently found that the extract was quite ineffective in lowering the blood-sugar of normal rabbits when administered in suspension by stomach-tube in doses equivalent to one-tenth of a pound of liver, a quantity which, according to Blotner and Murphy, is equivalent to about one unit of insulin. In our experience an injection of one unit of insulin produces a considerable fall in blood-sugar in the type of rabbits usually used for insulin assay.

Extracts were prepared from both fresh and frozen liver by the Blotner and Murphy process and extraction periods of both 12 and 48 hours were tried, but in no case was any hypoglycæmic effect observed. Liver Extract (Boots), prepared by the Medical Research Council's process (see THE LANCET, 1928, ii., 514), was also found to have no hypoglycæmic action. In fact, in practically all cases a slight but definite hyperglycæmia resulted. This is seen from the Table, which gives a few typical results compared with the blood-sugar fall obtained with the same rabbits following an injection of 1 unit of insulin.

CLINICAL AND LABORATORY NOTES

A NEW CLINICAL METHOD FOR THE ESTIMATION OF PROTEIN IN URINE.

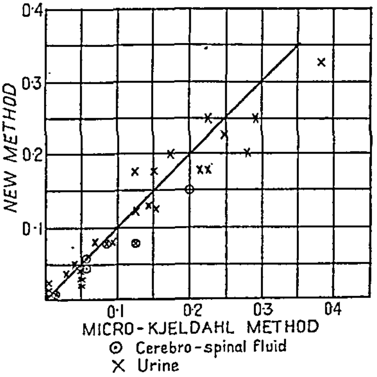
BY PHYLLIS M. TOOKEY KERRIDGE, M.SC.,
PH.D. LOND.,
LECTURER IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY, UNIVERSITY COLLEGE, LONDON.

(*From the Medical Unit, The London Hospital.*)

MOST of the methods of estimation of the protein content of urine in current use suffer from some disadvantage, either from unknown limits of error, or in the amount of time and skill required to carry them out. Determination by the micro-Kjeldahl method of the total and non-protein nitrogen, with calculation of the protein by difference, is satisfactory, but is laborious, and not very accurate when the protein N difference is small and the total and non-protein nitrogen amounts are large. The following method was devised in the course of work on the excretion of protein in nephritis, when a large number of analyses were required. It has been found to be simple and quick, and accurate enough for this and other purposes. It has also been found useful for protein nitrogen determinations in cerebro-spinal fluid. It can be done by a technician in three to four minutes.

Principle.—The urine is mixed with a carbon suspension and carbon and protein are simultaneously precipitated with trichloracetic acid. The greyness of the precipitate depends on the amount of protein, when the amount of carbon is constant. The tone is compared with standards.

Solutions required.—(*a*) Carbon suspension. The most convenient form is a 1 in 25 solution of "Higgins' Eternal Ink"[1] in distilled water. This is a black carbon fountain pen ink which has been a stable commercial product for over 30 years. It does not evaporate at a significant rate if kept in stoppered bottles. (*b*) Trichloracetic acid. 100 per cent. This concentration is greater than that often used for precipitation of proteins, but as a high concentration



Determinations of protein nitrogen by micro-Kjeldahl method and the new method. Readings in grammes of protein nitrogen per cent.

---

[1] Sold by Chas. M. Higgins and Co., 16, Farringdon-avenue, London, E.C., and 271, Ninth-street, Brooklyn, N.Y., U.S.A.

is necessary when dealing with very alkaline urines, it is used as a routine. The final concentration in the tubes is 10 per cent.

Standards.[2]—These were prepared from horse serum, which was obtained commercially. The protein N content was determined by the micro-Kjeldahl method, and amounts containing 0·25, 0·5, 0·75, 1·0, 1·5, 2·0, 3·0, 4·0 mg. protein N respectively were measured into 3 by $\frac{3}{8}$ in. tubes, using a graduated 1 c.cm. pipette, standardised by the National Physical Laboratory. The volume in each tube was made up to 1 c.cm. with distilled water. To each was added 0·1 c.cm. of solution A, and 0·1 c.cm. of solution B, and after vigorous shaking, each was corked. They have shown no signs of change during six months' use. The standards correspond to 0·025, 0·050, 0·075, 0·100, 0·150, 0·200, 0·300, 0·400 g. of protein N per cent., respectively, under the conditions of the test. Tones of grey half-way between any two of these standards tubes can be easily recognised.

Standards made from photographic greys, and from mixtures of kaolin and lamp black, &c., have been tried but are not satisfactory, owing to the difficulty in reproducing the bluish tone of the grey.

Procedure.—Pipette 1 c.cm. urine (or cerebro-spinal fluid) into a tube 3 by $\frac{3}{8}$ in. Add 0·1 c.cm. solution A. Shake. Add 0·1 c.cm. solution B. Shake vigorously. Compare grey with standards and read off per cent. protein N.

Accuracy.—The figure shows a comparison of determinations by this and the micro-Kjeldahl methods on protein-containing urines. Determinations on a few cerebro-spinal fluids have been included. The personal error is small. Determinations made by me and by a technical assistant did not ever differ by more than 0·025 g. protein N per cent. in the lower ranges, and by 0·05 g. protein N per cent. in the higher. The accuracy is unaffected by artificial light. It is considered to be adequate for many clinical purposes.

I am greatly indebted to Prof. Arthur Ellis for advice and criticism, and to the Medical Research Council for maintenance and expenses grants.

A CASE OF SPONTANEOUS PNEUMOTHORAX.

By G. B. Page, M.D. Edin., D.P.H.,
CLINICAL TUBERCULOSIS OFFICER, EXETER.

Cases of spontaneous pneumothorax arising during the course of manifest tuberculosis are not uncommon; cases arising in previously healthy persons are less frequent. It is well known that spontaneous pneumothorax may be the first sign of pulmonary tuberculosis—one of the dramatic modes of onset, like hæmoptysis. The following case seems worth recording on account of its benign character, and because the patient's family history on the one hand and his personal history on the other makes the cause doubtful.

The patient was a fairly well-developed youth of 19, previously healthy and of healthy habits, except for somewhat excessive cigarette smoking. His father died of pulmonary tuberculosis in 1927 after several years' illness; the paternal grandmother, uncle, and aunt also died of pulmonary tuberculosis. He worked in a garage.

On August 30th, while working on a car, he was suddenly seized with a gripping sensation referred to the lower end of the sternum. He had been eating pears, and described the feeling "as if a piece of pear had stuck on the way down." At first the symptoms were attributed to indigestion, but as the discomfort persisted and he became a little breathless he sent for Dr. E. Maberly, of Exeter. Dr. Maberly returned the same afternoon to make a more complete examination, and found a pleural rub in the left scapular and root regions. When in bed the patient was quite comfortable and not breathless. Knowing the family history, Dr. Maberly asked me to see the case with him. This I did on Sept. 1st, when examination revealed an apparently complete left-sided pneumothorax, the chief signs being absence of movement, hyper-resonance—especially at the axilla and base—absent breath sounds; with occasional metallic tinklings, the characteristic modification of vocal resonance, and the bell sound in perfection. Slight impairment of the right apex with prolonged expiratory phase was noted. There was no evidence of fluid on the affected side. Except for a little irritable, non-productive cough, and aching in the left shoulder, the patient felt quite well. Next day he was X rayed by Dr. D. Miller Muir, who reported that the left lung was completely collapsed and that the right lung showed increased root-shadows and lung-markings, with some abnormal opacities at the apex. The right side of the diaphragm moved normally, the left showing little movement. There was no sign of fluid. The heart was practically in the middle line (Fig. 1).

FIG. 1.

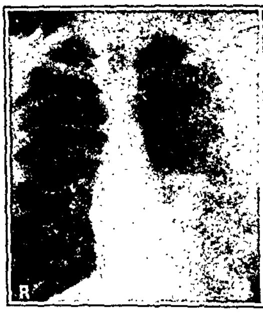


FIG. 2.

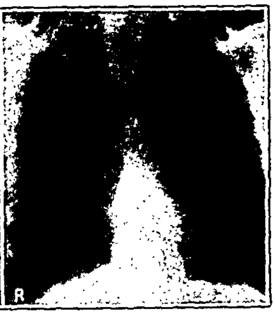

Recovery was uneventful. The patient was kept in bed until Sept. 16th, when he was allowed up for half an hour, the period being steadily increased until by the end of the month he was up nearly all day. The pulse and temperature were normal throughout and he felt well, except for a little palpitation. On Sept. 10th returning breath sounds were recognised in the upper part of the left chest, but signs of pneumothorax were still present, nor had the heart returned to its normal position. By Sept. 16th the bell sound had disappeared, but vocal resonance still had a metallic quality. On Sept. 24th the left chest was moving almost as well as the right, but there was still hyper-resonance in the axillary region. By Oct. 1st the lung was judged to have expanded, and this was confirmed by X ray examination on Oct. 7th. Dr. Miller Muir reported as follows: "The left lung now appears completely normal. The right lung does not look quite so congested as before, but it still shows increased root shadows, lung markings, and opacities at apex. The root of the left lung shows a few calcified opacities" (Fig. 2).

The patient's work necessitates lifting-strains, sometimes in a stooping position, but at the time of the accident he was, it is understood, lying across the top of a car. His family history makes infection with tuberculosis practically a certainty, and this is confirmed by the X ray findings, but there is no evidence of gross disease and no definite evidence that tuberculosis caused the spontaneous pneumothorax. Fortunately, in the course of a few years he will come into a business not requiring any physical exertion, so that he has been able to give up the garage work. The question of tuberculosis will be met by extended supervision and healthy living.

From the history of the case it may be judged that the rupture in the lung was small and collapse gradual, although finally complete. Such a case might quite easily be overlooked.

I am indebted to Dr. Maberly for asking me to see the case and permitting me to follow the convalescence, and to Dr. Miller Muir for radiological help.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF ELECTROTHERAPEUTICS AND COMPARATIVE MEDICINE.

AT a combined meeting of these Sections on Dec. 19th, with Prof. WOODBURN MORISON, President of the Section of Electrotherapeutics, in the chair, a discussion on

Radiological Problems in Man and Animals

was opened by Major A. A. PRYER. X rays were seldom used for diagnosis in the horse, he said. Owing to the size of this animal, and the thickness of its tissues, examination with ordinary radiographic apparatus was seldom successful. Nevertheless, the help he had received in this way made him think it would be worth while to set up more powerful apparatus which would be available when required. He had himself examined 70 living horses with X rays, making a total of 280 exposures. The difficulties encountered in interpreting the radiograms were enhanced in the case of the horse, but these were likely to be less when a number of veterinary surgeons had had a special training in radiology. Only a small proportion of horses could be X rayed, for they mostly resisted; the solution lay in a knowledge of the horse and an expert handling of it. Mechanical restraint, as by the use of ropes, was useless. Before applying the rays the horse should have had definite exercise and been on low diet, for both these measures made it less restive. The giving of an ounce or two of chloral hydrate was also useful, and the ears should be plugged. Before X raying the foot the shoes should be removed, otherwise they would scatter the rays. Major Pryer used a transformer set, giving 42 milliampères, exposed for two seconds, and worked at a distance of 26 inches. Fast work was necessary owing to the risk of the horse moving during the exposure. Practically only the horse's limbs and feet could usefully be radiographed. Peptic ulcers in the horse he had tried to see by X rays, but that was a disease which the horse rarely suffered from, and it had no gall-bladder. The most valuable field for X rays in the horse was the feet. Navicular disease was very common and a frequent accompaniment of this was the presence of spurs, which might occur without detectable areas of caries. The fluorescent screen he had found impracticable for equine work; a high power current was needed and the darkness was irksome to the patient.

Dr. R. W. A. SALMOND showed a slide of a pigmy elephant, in which he detected a bullet by means of X rays. For examining valuable hunters a movable apparatus would probably be required; it should be equal to showing details of a fractured limb by an exposure of a second or two; it should be as free as possible from noise and should not be brought nearer to the animal than about 12 inches. When the rays did not reveal a stone which was present he thought the technique could generally be blamed. When parasites happened to be present in air-containing spaces or were calcified, they were more easily seen than otherwise. Hydatid cysts, cysticercus, and trichinosis were detectable by the rays. Radioscopic examination was likely to increase in the future in the case of domestic pets which were ailing, for their lives were deemed sufficiently valuable to justify the expense. This method of examination of the joints and skeletons of animals could be of great use in determining the effects of various vitamins in the foods, and he regarded it as a valuable supplementary means of diagnosis, though not as a substitute for the usual clinical methods. A step which would lead to a much fuller use of radioscopy in animals was the setting up of installations in veterinary colleges and in the Army veterinary hospitals, as well as in the departments of zoology and anatomy in universities.

Lieut.-Colonel MIDDLETON PERRY spoke from the standpoint of the regular practising veterinary surgeon. In dogs, cats, and small animals calculi and tumours could usually be felt, and X rays were not needed. He stressed the need for training in the interpretation of radiograms; otherwise grotesque mistakes could easily be made. At present the chief use of the rays to the veterinarian was to assist in the diagnosis of obscure fractures, gall-stones, and foreign bodies. In using ultra-violet rays for animals he could obtain good results without first removing the hair if he continually brushed it up by the hand during the exposure. It was difficult to know how much diathermy could be tolerated by any given animal.

Dr. J. B. KING spoke of the work which had been done in the use of the rays in studying the œstral cycle in animals. In mice, A. S. Parkes found that while irradiation caused disappearance of Graafian follicles it did not influence the œstral cycle. Injections of pituitary extract, however, caused greatly increased activity of the follicles and of ovulation; with potent preparations of œstrin œstrus could be produced at will, but many preparations soon lost their power.

Prof. J. McCUNN said it was possible to detect odontomes in the head of the horse by means of X rays. The navicular bone was the bugbear of the veterinary surgeon and the side view was the most valuable for the detection of abnormalities in it. Sometimes caries was found to have eroded that bone to the depth of one-eighth of an inch. In the dog X rays could be of much more service than in the horse; particularly was the radiogram valuable in the detection of fractures and dislocations. Puppies could not be well seen in the uterus by the rays, probably because of the interposition of the amniotic fluid. He had not yet seen a case of pyloric stenosis in the dog, and gastric and duodenal ulcers were also rare in them. It was common, however, for dogs to suffer from osteosarcoma of the lower end of the radius. The use of the rays for sterilisation was but little required in animals; much more often the desire was to render sterile animals fertile, and for this ultra-violet rays were employed. There was good scope for radiology in animals, the obstacle was the expense.

Dr. A. E. BARCLAY contended that the possibilities of X rays in veterinary practice and zoology had not yet been properly explored. Cats were found to be very temperamental, while dogs bolted their food. A good animal to study by this means was the domestic hen, and an informing study had been made on the hen as to the actual mechanism of swallowing. The food was moved along not by the propulsion exerted by muscles squeezing it but by creating, periodically, a closed cavity between larynx and pharynx and then opening it and so causing suction. Defæcation had been studied in a similar way.

Dr. J. F. BRAILSFORD said that for the radioscopic examination of animals it was necessary to have the largest available apparatus. As the value of the rays in veterinary practice became more widely recognised he thought many practitioners would become owners of portable sets.

Dr. ALBERT EIDINOW spoke of the lethal action of the rays employed. Both man and animals could be killed by heat, and in the laboratory animals had been killed by pure visible light when photo-dynamic substances were used. As ultra-violet rays acted only on the surface of living tissues the area of application should be bereft of hair. Animals killed by ultra-violet light showed areas of necrosis in the skin and gut, and a hæmorrhagic condition in the lung; also a condition which he took to be thrombosis of the coronary vessels.

Prof. G. H. WOOLDRIDGE said that X rays were more useful for diagnosis than for treatment, but only in supplement to the usual clinical methods. Training was needed for the correct interpretation of radiograms. Sometimes in proved navicular disease no spurs were present. Sometimes urinary calculi in the dog were so small that X rays failed to reveal them. He could see in the extended use of X rays in studying animals a reason for a less frequent use of experiments in the teaching of physiology, and there must be distinct progress when radiology was more thoroughly taken up by veterinarians.

Dr. CHALMERS WATSON averred that the chief value of the radiographic study of animal conditions was in regard to diseases due to defective nutrition. Recently he had been studying in this way changes occurring in the joints and skeleton generally in poultry on an experimental poultry farm.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

AT a meeting held at Sheffield on Nov. 28th, 1930, with Dr. J. W. BURNS, the President, in the chair, a paper on

Obstructive Inflammatory Lesions of the Uterus

was read by Prof. DANIEL DOUGAL (Manchester). His remarks were based on a study of ten cases, and he considered that two factors were present in each of them—namely, an infection of the uterus and appendages, and atresia of some part of the genital canal. Since the menses never made their appearance, one or both factors must have been present at puberty, and the presumption was either that both were acquired during childhood, or that one, the atresia, was congenital, and the other, the inflammatory lesion, was acquired at a later date. He divided his cases into the following groups: (*a*) three in which the uterine cavity was obliterated; (*b*) two in which the uterine cavity contained mucus or caseous material (hydrometra or pyometra); and (*c*) five in which the uterine cavity contained menstrual blood (hæmatometra). He concluded that tuberculosis or some other acute infection of childhood may produce atresia of some part of the genital canal, the result as regards disturbance of function depending upon the place of the obstruction. In tubercle, the tubes and uterine cornua were the parts commonly affected, and their canals either became completely obliterated or distended with pus or blood. If the cavity of the uterus was obliterated, retained secretions or blood might be found in the tubes or cornua, but if the atresia was at the level of the internal os, there would usually be hæmatometra or pyometra. When the obstruction was below the level of the cervix, hydrometra was an additional possibility. It would be interesting, he said, to know something about the frequency of vaginal discharge in these diseases, and, more important still, to see the cases about puberty, when it might be possible to find out the extent of the damage to the uterus and appendages. A working arrangement was needed between the hospitals dealing with children's and infectious diseases and the gynæcological hospitals, to ensure that the cases were kept under observation until the effects, if any, on reproductive life had been determined. It would then be possible to trace the origin, not only of the serious lesions which he had described, but also of those less severe in which the tubes are sealed up or the ovaries adherent.

The PRESIDENT and Dr. A. A. GEMMELL each described a case which, in the light of Prof. Dougal's remarks, suggested they were not simple atresia, but the results of chronic inflammatory diseases.

Pathological Specimens.

Prof. Dougal showed a specimen of chorion epithelioma of the uterus which from the history had suggested retained products of conception, but which, on histological examination, showed the typical features of chorion epithelioma—viz., Langhans cells, *syncytium and chorion* wandering cells. He regarded chorion epithelioma as a very rare tumour worthy of record; he had only come across four cases during the past 12 years.—Mr. ERIC STACEY (Sheffield) showed a specimen of a twin pregnancy in which the first was born alive, and the second was a large hydatidiform mole, weighing 10 lb. 4 oz.—A further specimen shown by Prof. DOUGAL was a carcinoma in one horn of a double uterus. This consisted of a bicornuate uterus with a double cervix. In the right horn there was an advanced growth which had infiltrated the muscle wall and broken through into the lower part of the left horn and both halves of the cervix.—Mr. N. L. EDWARDS (Derby) showed a specimen of an ectopic gestation in a hydrosalpinx. This consisted of the left tube and ovary with a mole in the isthmic portion of the tube and a small tear in the wall through which intraperitoneal bleeding had occurred. The tube distal to the mole was thickened and in a state of hydrosalpinx. He wondered whether the case could be one of direct internal migration of ovum.—Mr. P. MALPAS (Liverpool) showed a specimen of a large cervical fibroid weighing $10\frac{1}{2}$ lb. with extensive cystic changes; also a specimen of a cervical fibroid removed subsequent to radium treatment of a coexistent carcinoma cervicis. The sections in this case were of interest, in that there was no definite change in the cells of the fibroid.

PRESENTATION HOSPITAL BEDS.—A bed has been presented to the Sick Children's Hospital, Aberdeen, as a memorial to the Aberdeen unit of the Royal Army Medical Corps who served in the late war.—The Hammersmith and North Kensington Licensed Victuallers' and Beer-Sellers' Protection Association has had a bed in the Devonshire Ward of the West London Hospital endowed in its names "in appreciation of the valuable help received through the members."—A bed in Urmston (Lancs) Cottage Hospital was recently dedicated to the memory of Dr. George Ernest Fryer, who was honorary medical officer of the institution from its foundation in 1897 to his death at the beginning of 1930.

REVIEWS AND NOTICES OF BOOKS

Deep X Ray Therapy in Malignant Disease.

A Report of an Investigation Carried out from 1924–1929 under the direction of the St. Bartholomew's Hospital Cancer Research Committee. By WALTER M. LEVITT, M.B., D.M.R.E. London: John Murray. 1930. Pp. 128. 10*s.* 6*d.*

THE Radiotherapeutic Research Department began work in 1924. It was decided at the outset that cases should be limited to four groups, corresponding to the groups in which research in radium treatment was being carried out. These groups were malignant disease of (1) breast; (2) uterus; (3) upper air passages; (4) œsophagus. To these were subsequently added (5) rectum, and (6) thyroid gland. The procedure for admission was as follows:—

> Cases were referred to treatment through a member of the Research Committee in charge of the appropriate group. With the exception of a few cases, any case in which radium could be used was so treated. If unsuitable, or too extensive for radium, the case was admitted for deep X ray treatment, unless generalised. Microscopic examination was the rule.

The stage of the disease at the commencement of treatment varied from group to group. In the Breast group (50 cases) the disease was usually far advanced, owing to the preference given to radium treatment in the more favourable cases. This must be borne in mind in judging the results. The split intensive dose gave better results than the single intensive method; thus 8 out of 28 cases treated by the split dose method showed disappearance of all signs of disease, but this primary response was not obtained in any of the 10 cases treated by the single dose method. In the Uterus group (containing a higher proportion of early cases) the primary results were encouraging. In 12 out of 16 cases of cervical cancer complete primary disappearance of signs of tumour was obtained. Recurrences were, however, frequent, which were improved though apparently not cured by subsequent radium treatment. In 4 out of 6 cases of carcinoma of the body of the uterus, evidence of disease disappeared and two remained well after four years. In the largest group, 170 cases of malignant disease of the Upper Air Passages, the best results were obtained with palatal growths. Four out of 7 palatal cancers and two endotheliomata were apparently cured; sarcoma of the pharynx gave three apparent cures out of seven cases. Sarcoma and endothelioma of the tonsil reacted well; carcinoma badly. Of post-cricoid carcinomata, 3 out of 11 were apparently cured, others reacted badly. 132 cases in the centre group were treated by X rays only, of whom 15 per cent. are now reported free from evidence of disease. In the Œsophageal and Rectal cases the results were not encouraging. Of the 319 cases of all types included in the whole report, 15 per cent. are now without evidence of disease. Definite palliative improvement was obtained in 60 per cent. of the remaining cases. The nature and degree of this improvement is clearly described in the report. The author states in his conclusion that malignant growths, even when advanced, may be made to disappear by X ray treatment, with freedom from recurrence for four years or even permanently; that the risks involved and discomforts to the patient are very small; and that in certain cases combination of X rays and radium is probably superior to either method alone.

This very bare summary of the figures does scant justice to the book as a whole. We would particularly commend to radiologists the excellent notes on technique—for example, the description of the six-field method due to Finzi for the treatment of laryngeal carcinomata by the intensive split dose method. The author's views upon the relative value of the split dose and the single dose methods merit careful attention, and his suggestions as to the best methods of combining X rays and radium are valuable in view of the growing importance of this method. Noteworthy also is his definite statement that out-patients react less well and suffer more from after-effects than in-patients. It is clear that adequate X ray treatment is hampered in this country by lack of bed accommodation. The statistical tables are numerous and very clearly arranged, giving the required information at a glance. Each is followed by a short analysis and comment. Every patient has been followed up and the ultimate result in each case is given.

Surgeons and practitioners will find this volume invaluable as a work of reference. The style is straightforward and free from technicalities. In scientific outlook, in freedom from bias, and in exact statement of facts Dr. Levitt's work compares very favourably with anything which has yet appeared on the subject.

Student's Handbook of Surgical Operations.

By Sir FREDERICK TREVES, F.R.C.S. Fifth edition. Revised by C. P. WAKELEY, F.R.C.S., F.R.S., Surgeon to King's College Hospital. London: Cassell and Co., Ltd. 1930. Pp. 535. 10*s.* 6*d.*

THE task of revising and modernising a text-book written nearly 40 years ago is no easy one if an attempt is made to preserve the traditional character of the book. Indeed, it is very questionable whether the outlook of the present-day surgeon has not changed to such a degree as to make the effort undesirable. It is the same sort of difficulty that is met with in trying to modernise a Shakespearean play. Nevertheless, Mr. Wakeley has accomplished the seemingly impossible. He has produced a book almost freed from the trammels of the past. A careful survey of it confirms the impression that it forms a very good guide to the student taking his operative surgery course. The number of illustrations has been very much increased and such subjects of recent interest as treatment by radium have been introduced. If one or two small points can be singled out for revision in future editions they are not of sufficient importance to detract from the general value of the book. It is to be hoped that at least two methods of excision for carcinoma of the rectum will be included in the future. At present there is none, yet the excessively rare operation for extirpation of an œsophageal pouch is described. Stovaine is recommended for spinal anæsthesia, although this has been given up in favour of novocain or percain by most recent exponents of the method. Ligature of the inferior thyroid artery is not described although it is an every-day operation. We find a good account of ligature of the innominate, a procedure which few surgeons have even seen and which we are assured is never the subject of an examination question. He recommends division of the thyroid isthmus early in the operation pharynx and then opening it and so causing suction. Defæcation had been studied in a similar way.

Dr. J. F. Brailsford said that for the radioscopic examination of animals it was necessary to have the largest available apparatus. As the value of the rays in veterinary practice became more widely recognised he thought many practitioners would become owners of portable sets.

Dr. Albert Eidinow spoke of the lethal action of the rays employed. Both man and animals could be killed by heat, and in the laboratory animals had been killed by pure visible light when photo-dynamic substances were used. As ultra-violet rays acted only on the surface of living tissues the area of application should be bereft of hair. Animals killed by ultra-violet light showed areas of necrosis in the skin and gut, and a hæmorrhagic condition in the lung; also a condition which he took to be thrombosis of the coronary vessels.

Prof. G. H. Wooldridge said that X rays were more useful for diagnosis than for treatment, but only in supplement to the usual clinical methods. Training was needed for the correct interpretation of radiograms. Sometimes in proved navicular disease no spurs were present. Sometimes urinary calculi in the dog were so small that X rays failed to reveal them. He could see in the extended use of X rays in studying animals a reason for a less frequent use of experiments in the teaching of physiology, and there must be distinct progress when radiology was more thoroughly taken up by veterinarians.

Dr. Chalmers Watson averred that the chief value of the radiographic study of animal conditions was in regard to diseases due to defective nutrition. Recently he had been studying in this way changes occurring in the joints and skeleton generally in poultry on an experimental poultry farm.

At a meeting held at Sheffield on Nov. 28th, 1930, with Dr. J. W. Burns, the President, in the chair, a paper on

Obstructive Inflammatory Lesions of the Uterus

was read by Prof. Daniel Dougal (Manchester). His remarks were based on a study of ten cases, and he considered that two factors were present in each of them—namely, an infection of the uterus and appendages, and atresia of some part of the genital canal. Since the menses never made their appearance, one or both factors must have been present at puberty, and the presumption was either that both were acquired during childhood, or that one, the atresia, was congenital, and the other, the inflammatory lesion, was acquired at a later date. He divided his cases into the following groups: (*a*) three in which the uterine cavity was obliterated; (*b*) two in which the uterine cavity contained mucus or caseous material (hydrometra or pyometra); and (*c*) five in which the uterine cavity contained menstrual blood (hæmatometra). He concluded that tuberculosis or some other acute infection of childhood may produce atresia of some part of the genital canal, the result as regards disturbance of function depending upon the place of the obstruction. In tubercle, the tubes and uterine cornua were the parts commonly affected, and their canals either became completely obliterated or distended with pus or blood. If the cavity of the uterus was obliterated, retained secretions or blood might be found in the tubes or cornua, but if the atresia was at the level of the internal os, there would usually be hæmatometra or pyometra. When the obstruction was below the level of the cervix, hydrometra was an additional possibility. It would be interesting, he said, to know something about the frequency of vaginal discharge in these diseases, and, more important still, to see the cases about puberty, when it might be possible to find out the extent of the damage to the uterus and appendages. A working arrangement was needed between the hospitals dealing with children's and infectious diseases and the gynæcological hospitals, to ensure that the cases were kept under observation until the effects, if any, on reproductive life had been determined. It would then be possible to trace the origin, not only of the serious lesions which he had described, but also of those less severe in which the tubes are sealed up or the ovaries adherent.

The President and Dr. A. A. Gemmell each described a case which, in the light of Prof. Dougal's remarks, suggested they were not simple atresia, but the results of chronic inflammatory diseases.

Pathological Specimens.

Prof. Dougal showed a specimen of chorion epithelioma of the uterus which from the history had suggested retained products of conception, but which, on histological examination, showed the typical features of chorion epithelioma—viz., Langhans cells, syncytium and chorion wandering cells. He regarded chorion epithelioma as a very rare tumour worthy of record; he had only come across four cases during the past 12 years.—Mr. Eric Stacey (Sheffield) showed a specimen of a twin pregnancy in which the first was born alive, and the second was a large hydatidiform mole, weighing 10 lb. 4 oz.—A further specimen shown by Prof. Dougal was a carcinoma in one horn of a double uterus. This consisted of a bicornuate uterus with a double cervix. In the right horn there was an advanced growth which had infiltrated the muscle wall and broken through into the lower part of the left horn and both halves of the cervix.—Mr. N. L. Edwards (Derby) showed a specimen of an ectopic gestation in a hydrosalpinx. This consisted of the left tube and ovary with a mole in the isthmic portion of the tube and a small tear in the wall through which intraperitoneal bleeding had occurred. The tube distal to the mole was thickened and in a state of hydrosalpinx. He wondered whether the case could be one of direct internal migration of ovum.—Mr. P. Malpas (Liverpool) showed a specimen of a large cervical fibroid weighing 10½ lb. with extensive cystic changes; also a specimen of a cervical fibroid removed subsequent to radium treatment of a coexistent carcinoma cervicis. The sections in this case were of interest, in that there was no definite change in the cells of the fibroid.

Presentation Hospital Beds.—A bed has been presented to the Sick Children's Hospital, Aberdeen, as a memorial to the Aberdeen unit of the Royal Army Medical Corps who served in the late war.—The Hammersmith and North Kensington Licensed Victuallers' and Beer-Sellers' Protection Association has had a bed in the Devonshire Ward of the West London Hospital endowed in its names "in appreciation of the valuable help received through the members."—A bed in Urmston (Lancs) Cottage Hospital was recently dedicated to the memory of Dr. George Ernest Fryer, who was honorary medical officer of the institution from its foundation in 1897 to his death at the beginning of 1930.

THE LANCET.

LONDON: SATURDAY, JANUARY 3, 1931.

THE STABILITY OF B C G.

The prophylactic administration of B C G vaccine by mouth to new-born infants, which has now been carried out in over 200,000 cases on the continent, has had a spectacular result which, at first sight, appears convincing. No ill-effects have been experienced at the time of vaccination—the Lübeck inquiry would have fastened on them had any been recorded—whilst the published figures show, in the case of infants born in a tuberculous household, that the infants have succumbed to tuberculosis with less frequency than have unvaccinated children in the same environment. The figures, however, have not been presented in a way that satisfies the trained statistician, and it may be long before valid conclusions can be drawn. The vaccine, as everyone knows, consists of living tubercle bacilli of extremely low virulence which, it is believed, do not produce progressive tuberculosis. When we turn to the question of the fate of these living bacilli after ingestion by the infants, we are however on insecure ground. Numerous records have shown that a positive tuberculin reaction is acquired by the infants within a few weeks, a fact which would suggest that some tissue response takes place, but not much information is yet available as to the actual fate of the bacilli. Do they penetrate into the intestinal mucous membrane, and if so with what result? Are they immediately destroyed by the tissues or do they produce in the mesenteric glands the non-progressive lesions reported as sometimes occurring in laboratory animals, gradually dying out in the course of a year or two, but producing immunity meanwhile? The number of children vaccinated by subcutaneous or intramuscular routes where the effects can be seen is small, but it appears that local abscesses sometimes result, and where these occur we cannot be sure that more untoward results may not follow. Indeed we think there is evidence from some of the reported cases that untoward results have occasionally followed. But whether similar effects may sometimes occur in mesenteric glands after oral ingestion it is impossible to say, since the glands are not readily accessible to examination.

The researches carried out on laboratory animals with the vaccine have led to somewhat varying results. In the majority of instances the vaccine has been given by the subcutaneous route, and here again in some cases local or non-progressive tuberculous lesions have resulted. Every now and then an instance is reported of progressive tuberculosis becoming generalised and ending fatally. We publish on another page a record of work of this kind done at the Oxford School of Pathology by a new technique. In the course of experimental work Prof. Dreyer noted that a certain human strain of tubercle bacillus, which had been subcultured on artificial media for several years, would grow on ordinary veal-peptone broth, and, further, that if the inoculum, instead of being floated on the surface of the broth, was submerged in its depths, growth occurred in the form of small granules at the bottom of the flask, the supernatant fluid remaining quite clear. The method results in growth which is very slow and never abundant, but occasionally the tubercle bacilli grown in this manner are much more virulent than when grown on current media. Prof. Dreyer has applied this technique to the bacillus of Calmette-Guérin. Two strains were investigated, one of them, B C G (1), from the National Institute for Medical Research, which up to the time of experimentation had been completely avirulent for laboratory animals; the other, B C G (359), received from Prof. Calmette through the Medical Research Council. Deep broth subcultures of B C G (1) produced generalised tuberculosis in all of 28 guinea-pigs inoculated intraperitoneally, and severe progressive tuberculosis in all of 12 rabbits inoculated intravenously. In the case of B C G (359) only one of 20 guinea-pigs inoculated with the original culture, as received from the Pasteur Institute, had localised caseous tuberculous lesions, and another had several healing lesions. Deep broth subcultures of this strain showed progressive tuberculous lesions in a few cases, but the series has not yet been concluded. The evidence so far obtained suggests, however, that B C G is not so stable in culture as was at first believed. Two cultures, from a rabbit and a guinea-pig respectively, in the series of animals infected with deep broth cultures of B C G (1) were submitted by Prof. Dreyer to Dr. Stanley Griffith for an opinion; he reported that the cultures were mammalian but did not conform exactly either to the human or bovine type. Dr. Griffith found both strains virulent for the guinea-pig, producing typical general tuberculosis, but of relatively low virulence for the rabbit with effects not exceeding in severity those which are sometimes produced by standard human bacilli. Dr. Griffith considered the number of tests too small to base a definite conclusion upon, but the results are irregular and confusing.

Prof. Dreyer is in agreement with Petroff and Watson that in the great majority of experiments on the pathogenicity of B C G the animals have been killed too soon after inoculation. A prolonged latent stage in an apparently benign infection cannot be taken as a criterion of the final outcome—a point to be borne in mind when drawing an analogy with vaccinated children. Prof. Dreyer discusses the results obtained with a B C G strain in which Petroff isolated smooth and rough colonies, the lesions produced in animals by the rough colonies showing a tendency to heal and those produced by the smooth colonies invariably showing progressive tuberculosis in guinea-pigs and occasionally in rabbits. Petroff's virulent strain was produced by growing the culture in other than the glycerin-bile-potato medium recommended by Calmette:

and it has been suggested that admixture with another strain of tubercle bacillus may have occurred. At all events we are not aware that Petroff's results have yet been fully confirmed. The important point, however, is that Prof. Dreyer has now shown, what had previously been claimed by Malkani and other workers, that if B C G be subcultured on other media than the glycerin-bile-potato, to which Calmette has accustomed it for many years, virulent subcultures can be obtained; all this strengthens Petroff's contention that the human body cannot be compared to glycerin-bile-potato as a medium for the growth of B C G. The question remains open as to whether, as Prof. Dreyer indicates, pathogenic variants of B C G may not arise from time to time. There is a strong feeling in this country that the stability of the B C G strain should be more carefully substantiated before it is used as a vaccine. The same caution has been shown by the central German health authority in reaffirming its disapproval of the use of living bacilli for prophylactic treatment in human beings until our experience is more precise. The decision was no doubt a result of Prof. Bruno Lange's report[1] on the Lübeck incident which, while discarding any assumption that the Lübeck disaster was caused by a spontaneous rise in virulence of the B C G vaccine, yet left it open whether or no under laboratory conditions the strain might not again become virulent.

CAPITAL PUNISHMENT.

By recommending the abolition of the death penalty for an experimental period of five years, the report from the Select Committee on Capital Punishment (summarised on p. 44) has opened up again a problem that involves totally different questions. We may assume that punishment of any kind originally depended upon the principle of an eye for an eye, a principle so deeply rooted that it appears to many people as an axiom in need of no justification, and is defended with the vigour that marks the defence of any strong belief accepted without question. Nevertheless, the origin of the principle is only occasionally admitted and it is often supported by an appeal to a secondary consideration, the need to protect society. This protection is sought in the salutary effect of punishment upon the offender or—the only social benefit claimed for the death penalty—in its deterrent effect upon those who, in the absence of the penalty, would be tempted into crime. The idea of a lethal chamber for people unfit to be members of our social order is sometimes put forward, but has no relation to ceremonial hanging as a punishment.

That the salutary effect of punishment is proportionate to its severity was long taken for granted, and only in recent years has the study of penology led to a reconsideration of the assumption. As a result many changes have been made, and in the handling of first offenders we try to avoid that punishment which was at one time *automatically* inflicted. Crime has not increased as a consequence, while the lightening of penalties has made almost incredible the savage punishments inflicted a century ago and then regarded as necessary. The lex talionis, which satisfies something primitive in our nature, thus serving as a force in social development, is no longer the main guiding principle of our penal laws. These now have as their aim not merely the infliction of a punishment that will cancel out the offence, though that element is still present, but rather the reformation of the offender. We still have some distance to travel before we shall have applied to criminal procedures all our recently acquired knowledge of the motives underlying conduct, yet it is recognised that savage punishments defeat the immediate aim of reforming the offender, and are lacking in their supposed deterrent effect upon others. There are brutal natures for whom severe punishment still seems necessary, but even in such cases the automatic infliction of the punishment has results that need watching, for they may not be what we expect. The terrorising effect of punishment, or of the prospect of it, must not lead us to picture the potential criminal weighing the pros and cons of an intended crime and then coming to a decision; the experienced offender might do that, but then it is probably a business question affecting his livelihood.

Capital punishment has two functions, first to satisfy the desire for vengeance upon the particular criminal, and, secondly, to terrorise other would-be murderers so that they will refrain from their premeditated crime. The deliberate intent to murder is so foreign to us that we can scarcely judge of the thoughts of a man bent on such a deed, but it is possible to imagine him salving such conscience as he might possess by reasoning that he is taking the risk of the same fate as his victim. This is one argument of those who would deny the deterrent effect of the hanging penalty, and the frequent combination of murder with suicide gives plausibility to it. Perhaps an execution that made the greatest possible appeal to the sentiment of social vengeance was that of the murderer of police-constable Gutteridge three years ago. This deliberate and brutal crime was committed by a man who had already undergone severe punishment at the hands of the law and must have had a full realisation of its power. In spite of his attempts at suicide in prison he was duly hanged, and the sentiment of vengeance was appeased. It is difficult to recall a case in which hanging was more justifiable or in which the death penalty as a deterrent had been more futile, for, unlike many murderers, this man may be assumed to have faced the probable consequence of his action. So great was the public's satisfaction at his execution that it ignored the question of how it came about that such a criminal could mature in our midst, a question the answer to which is of more importance than the hanging of half a dozen murderers. Every murder is an example of the failure of the death penalty to deter, and we have no knowledge that can justify the *assumption* that the removal of a penalty surviving from more barbaric times will be followed by an increase of the crime it is supposed to prevent. We must keep separate our two motives for inflicting the death penalty, the sentimental desire to satisfy the lex talionis, and the practical aim of preventing more murder. The first motive we can weigh in the balance against what we like to believe are the more humane sentiments of the present day, and as to the second, we may look to the experience of other countries where the penalty has been abolished. There is no reason to fear that the experimental abolition proposed by the Committee will lead anyone to consider the advantages that penal servitude has over hanging before deciding to kill a fellow man.

---

A RESEARCH INSTITUTE FOR SURGEONS.

A POLICY recently initiated by the Council of the Royal College of Surgeons of England has not received the attention it deserves, for if it prospers it will give England what it now lacks—an institute where surgeons can carry out experimental research bearing on their art. At the present moment there are young men aiming at becoming members of the surgical staffs of our teaching hospitals who have ideas which they wish to put to the test of experiment, but are frustrated by two obstacles. The first is lack of income; to make a living they have to devote their time to "coaching" and to routine duties; the second is that there is no institute to provide them with the means of carrying out their inquiries. The policy which is now being carried out by the Council of the College, under the enterprising leadership of its President, aims at removing both of these handicaps. During the past year the Council has built and equipped two laboratories for surgical research in the College buildings; these, we learn, are now occupied. Research scholarships have been instituted. Lord MOYNIHAN appealed to Lord BEAVERBROOK, Lord MELCHETT, Sir BERNHARD BARON; each endowed a scholarship for seven years—yielding the holder £500 per annum. The Council instituted a scholarship of the same value. Two scholars have been appointed; two more will be elected early in 1931. It has also been determined, wisely we think, that the men who hold such scholarships should retain their connexion with their hospitals. Thus the College has deliberately embarked on a scheme which it is hoped will ultimately make London a centre of surgical research for the Empire.

Only those who are familiar with the history of our English College and of its great museum will appreciate what this new departure in policy implies. Hitherto the official attitude has been not to devise experiments but to wait until disease has made them in the human body, and from these undesigned experiments draw such conclusions as could be warranted. Ever since 1800, when the College built its museum on the south side of Lincoln's Inn-fields to house the Hunterian collection, the Council and its officers have been content to preserve and to study merely the savage records of disease; their museum has become the greatest medical treasury in the world. It is true that there have been officers connected with the museum such as the late Prof. S. G. SHATTOCK, who did resort to deliberate experiment to throw light on morbid processes, but such inquiries were made outside the College. Thus it remains true that in the main the policy pursued has been one of patient watching and waiting for disease to make its own revelations. Henceforth the Council is committed to active research as well as to passive inquiry as a means of advancing the surgeon's power as healer. Nor in adopting this extension of policy are our surgical leaders blind to the fact that the gift of devising and carrying out experiments so that they will elucidate the processes of disease is one of the rarest endowments—one given only to a fortunate few. It is certainly important for the progress of surgery that such gifted young men should be given their opportunity.

The scheme as outlined marks only the beginning of a movement. There are portents which lead one to suspect that there will be a great extension in the near future. Mr. G. BUCKSTON BROWNE, who two years ago presented Darwin's home at Downe, Kent—only 16 miles from Charing Cross—to the British Association as a national possession has the establishment of a surgical institute very much at heart. He is desirous that part of the land attached to Darwin's home may be used for the erection of such an institute—one to be conducted as an extension of the scheme already established in connexion with the museum. Lord MOYNIHAN, mindful of the fact that John Hunter advanced surgery as much by experiments conducted at his farm at Earl's Court as by his clinical and pathological observations at St. George's Hospital, is also desirous of seeing an "Earl's Court" instituted in connexion with the College at Charles Darwin's old home. With such support behind it we have every reason to hope and believe that a research institute for surgeons will materialise in the near future.

MODERN PSYCHOLOGY AND THE PRACTITIONER.

THE development of modern psychology has been too sudden for easy acceptance. It has not so much grown by simple accretion from previous knowledge, as been hacked anew from bedrock by rough tools. Still far from complete, its present form, though strange and sometimes at first sight even revolting when judged by classical standards, is convincing enough to make it seem impossible that a pretty statue of reason on a pedestal will ever again be accepted in its place. The dethronement of reason and the recognition of wishes, direct and indirect, as the most powerful, if not the only motives influencing conduct—these things form corollaries of the new conception of the mind and the mechanisms by which it functions. They are now widely accepted, although still largely ignored by the law-courts and other fields of scientific investigation. Since the scientific writers mostly represent thinking types, whether extrovert or introvert, the criteria by which scientific evidence is weighed are not seriously menaced. But there are signs that the law-courts throughout the world will sooner or later have to adjust their procedure in accordance with the deeper knowledge of mental processes revealed by analytical research. The attitude of the intelligentsia of all civilised countries to these matters is well summarised in the following passage taken from the *Week End Review* of Nov. 27th, 1930.

> "Sadism, and masochism, œdipus and inferiority complexes, homosexual and mother fixations, all these have passed out, in the last few years of mental revolution, from the psychological study into the street. For a little while we were shocked, but already to the whole gamut we are become immune. We take them for granted like peristalsis."

Many doctors are quite aware that their busy life has prevented them from appreciating a change of outlook which may be familiar to large sections of their patients. Some doctors remain aloof and disapproving. Most regret that they have had no time to read and assess for themselves the bulky tomes which until quite recent years were the only reliable source of information on the schools of thought which have arisen since Freud revolutionised psychological medicine. For doctors who wish to study mainly abnormal psychology and its treatment Dr. Bernard Hart,[1] more recently Dr. Maurice Nicoll [2] and Dr. Emanuel Miller [3] among others have provided excellent short surveys. Current ideas on the mechanism of the normal mind are less easy to come by. A clear and simple introduction to this difficult subject was given in a course of lectures recently delivered by Dr. E. Graham Howe on behalf of the Tavistock Clinic, and noticed in The Lancet of Dec. 20th. We have now arranged for the publication of these 12 lectures in serial form in The Lancet, the first lecture appearing in this issue. The attendance at these lectures and at those on Type Psychology which followed them on Wednesday afternoons was maintained throughout the session. We have reason to believe that the wider audience to which they can appeal in our columns will be equally appreciative of the directness and fairness of Dr. Howe's exposition of a most difficult subject. There seems no doubt that if the family doctor is to resume the friendly rôle even of guide, let alone that of philosopher, in behalf of his patients, he will have to subdue such prejudices as his training in organic neurology may have given him and master, even if he does not altogether accept, current ideas on psychology.

ANNOTATIONS

SERUM TREATMENT OF PNEUMONIA.

The search for a specific remedy for lobar pneumonia has been complicated by the fact that the causal organism, the pneumococcus, comprises several distinct serological types. For practical purposes three definite groups are recognised (1, 2, and 3), while all the other strains are classed together in a heterogeneous group 4. An antipneumococcal serum will only agglutinate strains of the same group, and must therefore be appropriate in every case. It has proved difficult, moreover, to prepare an effective serum because the pneumococcus does not produce either exotoxin or endotoxin, and its antisera must therefore be antibacterial instead of antitoxic. Attempts to make a serum of this kind have been partially successful for types 1 and 2, which are responsible for 50 to 75 per cent. of all cases of pneumonia, but so far no serum has been of any value against the other types. Furthermore, the serum available has been of very low titre, so that very large amounts are necessary to get any therapeutic effect, and it must be given soon after the onset of the disease if it is to do good. Hence it is not surprising that most clinicians prefer to keep to old-fashioned methods rather than worry their patients, who are very ill, with frequent intravenous injections—not to mention the dangers incidental to large doses of horse serum.

Five years ago L. D. Felton succeeded in preparing a more concentrated polyvalent antiserum by immunising horses with types 1, 2, and 3. The serum was obtained in the usual way, but the immune bodies were reprecipitated by distilled water and were then dissolved again in a concentrate said to be 10 to 20 times as strong. The amount of foreign protein in this serum was much reduced, and the likelihood of so-called anaphylactic reactions was thereby lessened. The serum was standardised in units, a unit being the amount of serum that will protect a mouse against a million fatal doses of pneumococcal culture, and the relative potency for the three types is shown by the fact that a given amount of serum will contain 2000 units against types 1 and 2, and 300 units against type 3. R. L. Cecil[1] tried the remedy in 414 alternate consecutive pneumonia cases admitted to the Bellevue Hospital, giving it immediately after diagnosis, without waiting for the organism to be typed, and his results suggested that it definitely reduced the mortality in types 1 and 2. The mortality in type 3 was 10 per cent. more in the treated cases than in the controls, while in type 4 it was 10 per cent. less. More recently, with Plummer,[2] Cecil has published another report from the Bellevue Hospital in which it is shown that Felton's serum is more than ten times as potent as unconcentrated serum and that in a series of 239 cases of type 1 infection treated with serum the mortality was only 20 per cent. compared with 30 per cent. in a control series of 234. They further found that this mortality was reduced to 12 per cent. when the cases were treated within three days of onset. In their opinion the use of this serum has now passed beyond the experimental stage, and they think that if it is given early in adequate amount its beneficial effects are certain. To some extent this claim is supported by the papers from Scotland published in our last issue. In Edinburgh Felton's serum was given to every second case of lobar pneumonia admitted to the Royal Infirmary over a period of ten weeks, and comparison with the alternate controls suggests that it is definitely remedial in types 1 and 2. Apart from lower mortality, it was noticed that half the serum-treated cases had their crises on or before the fifth day—the proportion among the controls was under 20 per cent.—and certain cases seemed more comfortable for their treatment, although their illness was not shortened. At Glasgow Royal Infirmary the serum was given to 58 consecutive cases of lobar pneumonia immediately after admission and before they had been typed. These cases were compared with a control series from previous years who, but for serum, had been treated in just the same way. The age-incidence in the two groups corresponded very closely, and it was again found that the mortality in the serum-treated group was appreciably less in both male and female patients. Both in the Edinburgh and Glasgow series there were anaphylactic reactions in several patients, despite preliminary tests to detect supersensitiveness.

[2] Jour. Amer. Med. Assoc., Nov. 22nd, 1930, p. 1548.

The considered conclusions from the two great Scottish schools are expressed with commendable discretion, and the writers hesitate to draw conclusions from their comparatively small material. Statistics about a disease like lobar pneumonia are liable to distortion by such factors as the age of the patients, a variation in virulence from year to year, the day of disease on which treatment begins, and the incidence of complications not due to the pneumococcus. None the less, so far as it goes, it is noteworthy that opinion on both sides of the Atlantic is agreed about the value of Felton's antiserum.

A PROBLEM OF THE HOP-FIELDS.

HOP-PICKING sets the county health authority in Kent a problem of some difficulty. To the rural areas around Maidstone and Tonbridge, with a population of 50,000, there come year by year in September 60,000 East-Londoners to pick the hops, reinforced, especially at week-ends, by another 40,000 or so of relatives and visitors, who act as though it is up to the hop-growers to provide free holiday and convalescent camps for all of them. As a rule the hop-growers do recognise their responsibilities to the pickers, although there are occasional prosecutions for failure to scavenge, to provide cooking arrangements, weather-proof huts, adequate water-supply, and sanitary accommodation. Among the exceptions mentioned by Dr. S. N. Galbraith, medical officer of health for the S.W. Kent united area, is a grower who has paid since 1926 over £70 in fines and costs, which would have gone a long way to carry out the needful instalments. Various voluntary organisations provide dispensaries and nurses for the sick, but a nice point has arisen as to who should provide hospital accommodation for infectious diseases. Dr. Galbraith points out that diseases which occur among the hoppers are mostly contracted in London and can readily be sent to the London fever hospitals. It would be unreasonable in his opinion for the rural districts to provide additional accommodation for a migration which lasts at most for one month each year. The case is not parallel with that of seaside resorts, whose population may be doubled by visitors for three to six months in the year. The help of the London County Council and the metropolitan borough councils has, however, been invoked hitherto without success. While the Ministry of Health does not give rulings on legal questions, it considers that in general the responsibility for dealing with infectious disease rests with the local authority in whose area the cases occur. The attempt to prevent infectious cases or their contacts from access to the camps has not met with much success, although some contacts were sent back last year. Londoners prefer, as Dr. Galbraith remarks, to have their sick in hospitals with which they are familiar, and do not like leaving their children behind in a rural hospital at the end of the picking season. The present practice, it seems, is apt to lead to the concealment of disease. Dr. Galbraith cites the case of a woman who infected her father with small-pox before leaving London, and subsequently infected her son aged 5 years in the camp. Mother and son travelled from the hop-fields to London by train and bus, and were then removed to the L.C.C. fever hospital. If she had reported sick on the farm, local small-pox accommodation must be provided at the expense of Kentish ratepayers. The problem should be susceptible to equitable compromise between the authorities concerned, for the hopper-camps, if properly sanified, should benefit both the health and the economic position of a large section of neediest Londoners.

ORAL ANTI-DIABETIC REMEDIES.

SINCE the discovery by von Mering and Minkowski in 1889 that the pancreas is intimately related to the causation of diabetes mellitus, countless workers have attempted to treat this disease with substances administered by mouth. Thus there is a long and it must be confessed dismal history of various pancreatic preparations which when given by mouth were claimed to effect a reduction in the blood-sugar and urine-sugar content. The commercial exploitation of this type of remedy formed a distressing chapter in the story of endocrinology, when, fortunately, the discovery of insulin gave such clear-cut results that these older preparations fell into deserved disrepute. Since then the problem has mainly centred round the oral administration of insulin itself, various attempts to solve it having been made by many reputable workers.[1] A new line of approach has been opened up by H. Blotner and W. P. Murphy,[2] who described the effect of liver feeding upon the blood-sugar, and maintained that a substance could be prepared from liver which was capable of reducing the blood-sugar. This was all the more remarkable since the action was definitely present when the liver or liver extract was administered orally. The hope was expressed that these substances might prove a valuable adjunct in the treatment of diabetes, and confirmation and report of their use has been anxiously awaited. Not long ago R. D. Lawrence in this journal[3] described a clinical experiment in which an extract made after the method of Blotner and Murphy was tried. He was unfortunately unable to confirm the claims made by the American workers, and showed conclusively that the extract employed by him had no effect upon a very carefully standardised diabetic patient. In our present issue will be found a paper by Dr. P. C. Brett and co-workers in which the problem is tackled from the laboratory point of view. Working in the laboratory of a commercial firm manufacturing insulin, they had at their disposal a large number of rabbits whose response to the international standard of insulin was well known. Using this colony of rabbits they proved that a substance made by the method of Blotner and Murphy was completely inactive. These carefully controlled animal experiments, taken in conjunction with the clinical experiment of Lawrence, seem to contradict the earlier publication of the American workers, and unless some discrepancy in the method of preparation can be discovered it appears that yet another claim to have found an oral substitute for insulin must be abandoned.

THE TRAFFIC IN DANGEROUS DRUGS.

FURTHER attempts to give effect to the limitation of the production of narcotic drugs to the amounts required for legitimate medical purposes, to which allusion was made in THE LANCET of July 26th last, have been made under the auspices of the League of Nations. In September the Assembly unanimously resolved that plans should be prepared for effecting this desirable limitation, and in pursuance of this object the Council proceeded to convene two conferences. One of them, consisting of representatives of producing countries, was held in London on Oct. 27th to Nov. 11th, and its report has just been made public. The other conference, at which both consuming and producing countries will be represented, is to be held in Geneva next May. Nine countries sent representatives to the London conference, including three—Soviet Russia, the United States, and Turkey—which are not members of the League of Nations. Attempts were made at the conference to arrive at agreed quotas which the producing countries should be permitted to manufacture and export; but while success did not attend its efforts in respect of morphine and heroin a provisional agreement was reached in regard to the production of cocaine. A comparison of the quotas suggested by the manufacturers showed no apparent relation to the figures furnished to the secretariat of the League of the actual national exports of the drugs in question during recent years. Further consideration and negotiations are to be proceeded with before the Opium Advisory Committee of the League meets this month in the hope that a draft Convention dealing with the method and control of limitation of output may be laid before the full Conference in May next. It appears that the draft plan, which was the outcome of the London conference, was accompanied by reservations to its proposals on the part of Japan, Soviet Russia, and Turkey. Perhaps the most arresting features in connexion with the London conference were the participation of representatives of Turkey in the deliberations and the disclosures they vouchsafed in regard to the export trade of that country in narcotics. Turkey, as is well known, is one of the largest opium-producing countries in the world, and moreover it has hitherto refrained from signing either The Hague Opium Convention of 1912 or that of Geneva in 1925. It has been a startling revelation to find that there are now in Constantinople three drug factories, the largest of which has been set up by persons whose licences were confiscated by the French Government as the outcome of illicit traffic. From these factories it appears that more than 4000 kg. of morphine and more than 8000 kg. of heroin are being annually exported. As none of the countries to which it was stated consignments had been despatched had reported their receipt to the Central Opium Board it can be reasonably concluded that much of the seizures of contraband which have been reported from China, New York, Marseilles, Rotterdam, and Hamburg may have emanated from these enterprising drug factories in Constantinople. There will be ample material for consideration by the Council and Assembly of the League of Nations, as well as its Advisory Committee and Permanent Central Board, if the limitation of production of opium and its derivatives and cocaine to medical and legitimate purposes is to be achieved in accordance with The Hague Convention of 18 years ago and the more recent engagements entered into at Geneva in 1925

THE CONWAY LETTERS.

Dr. Archibald Malloch wrought better than he knew when he published in 1917 a short account of "Finch and Baines: a Seventeenth Century Friendship." It has incited Miss Nicolson to collect and annotate the Conway letters which are now published [1] at the expense of the Kingsley Trust Association Publication Fund, established by the Scroll and Key Society of Yale College. Miss Nicolson has performed her editorial task admirably, and shows how wide is her knowledge of the period and of the chief factors in it. She has prefixed to each chapter a general introduction, whilst the letters themselves are carefully annotated with sufficient illustration to help the general reader without detracting from the continuity of the story. The volume contains 281 letters and is nearly exhaustive, but when she is preparing the second edition, which will undoubtedly be called for, she should take the opportunity of consulting the Rev. John Ward's Diary, which was sold at Sotheby's in 1928, and is at present in the United States. John Ward was vicar of Stratford-on-Avon when Anne Conway was at Ragley. He has much to say about events there, and was not backward in expressing his opinion of Dr. Henry Stubbes, physician and author and friend of Hobbes.

Anne Conway, by and to whom most of the letters were written, was a remarkable woman, learned beyond her time. She was loving and beloved by all with whom she was brought into contact; to her devoted brother and affectionate husband she was "my dearest dear." Yet she suffered so severely from a constant headache—perhaps due to a chronic sinus infection, for it was certainly no ordinary form of migraine—that a great part of her life was spent in darkness and seclusion at Ragley, near Alcester, in Warwickshire. Born Anne Finch on Dec. 14th, 1631—a date for which Prof. Nicolson must be thanked—she married in 1651 Edward Conway, son of the second Viscount Conway and Killtulagh, county Antrim, where the Marquisate of Hertford still holds estates, and in due course became Viscountess Conway. Yet it is not as a titled lady of the Restoration period that we think of her, but as the humble-minded friend of Henry More, the scholar, mystic and Christian Platonist of Christ's College, Cambridge; as the patient invalid who was unsuccessfully treated by Valentine Greatrakes, the altruistic "Stroaker"; and as the pupil of Francis Van Helmont and Johann *Gottfried* von Leibniz, who led her from the speculative fields of mysticism to the more healthy atmosphere of the Society of Friends, commonly called Quakers. The letters contain much that is interesting to members of the medical profession. Her eldest brother, Heneage Finch, married Elizabeth, daughter of Daniel Harvey, and she was thus related to Dr. William Harvey by whom she was treated. Her father-in-law, Lord Conway, writes of him in faint praise on July 1st, 1651:—

---

[1] Conway Letters. The Correspondence of Anne, Viscountess Conway, Henry More, and their *Friends, 1642–1684*. Collected from Manuscript Sources and Edited with a Biographical Account by Marjorie Hope Nicolson, Professor of English in Smith College, New Haven. Yale University Press. London: Humphrey Milford, Oxford University Press. 1930. Pp. 517, with 16 illustrations. 24s. net.

> "To have a physician abound in phantasie is a very perilous thing. If I had not a great desire to keep you I would not write anything against Doctor Harvey which might in any kind deem to prejudice him, for I do greatly esteem and value him, but I think this is truth as it is that I believe that my son would not know where to find such a wife nor I such a daughter, therefore I pray preserve yourself for your own sake, and then, if there be any place left, for your most affectionate father."

Perhaps Lord Conway was right, for all other measures having failed Harvey was suggesting that she should go to Paris to be trephined—then a formidable and often fatal operation.

Not the least interesting of the letters is that written by John Finch to his sister. It is dated Paris, Dec. 1/11, 1651, and he says, amongst other things:—

> "The Hotel Dieu, God's house, next to the Church of Nostre Dame is, I believe, the best hospital in the world either in respect of the numbers of the sick persons which is above 2000 or their accommodation, which is as good as any sick person requires, save that the multitude of the diseased makes them forced to lay six or eight in one bed, which hinders certainly the recovery of many and infects others fully, that had but a little beginning of a disease in them. 'Tis to me a strange thing to see how many persons of quality come thither, their charitable dispositions making them dispense with that offensive smell which cannot but be very great where so many persons diseased infect the air. There are, besides them that daily come, some religious women who, abandoning all the world, give themselves wholly to attend the diseased in the most servile offices you can imagine. There is scarce ever a night in the year but some die out of this place. I went into the Kitchen belonging to this hospital and I see at least twelve or 14 spits of meat, of fowl and other provision roasting, which lasts from morning to night, as soon as any spit is roasted, a new one supplying its place. But besides for broth I think was meat enough in three cauldrons to supply an army which yielded a perpetual quantity of broth."

All the letters are worth reading, though a few, like those describing the Fire of London, have already been printed. The first is dated May 13th, 1640, and the last sad one of Feb. 18th, 1678/9 gives an account of Lady Conway's death and Van Helmont's device of preserving her body in alcohol until the arrival of her husband from Ireland. She is buried in the quiet little church at Arrow.

THE HEALTH OF THE SCHOOL-CHILD.

THE annual report of the Chief Medical Officer of the Board of Education summarises the work among school-children in 1929.[1] Under statutory obligation nearly two million children were inspected—a decrease of 80,000 on 1928—and in addition pre- and post-school children are being examined in steadily increasing numbers. The percentage of children found to be suffering from defect remains around 20, the decimal figure being higher this year than for the preceding three years. Prolonged—some say unprecedented—industrial depression has led to a special inquiry into the incidence of malnutrition; this has revealed an increase in "borderline" cases, but no very great increase in the definitely ill-nourished. This is a tribute to the services of the organisations attempting to relieve distress in mining and other districts, but the position is still an anxious one, and the efforts must not be relaxed. Apart from special industrial districts, the children of the country seem on the whole to be improving in health and hygiene. Nevertheless a large amount of preventable illness and suffering still exists, and the report contains a special section on the teaching of hygiene. Returns have been obtained from a number of schools, arbitrarily selected, and a total of 3033 reports has been received on the subject. The replies show that health teaching is very unevenly given, some schools paying much attention to it and others ignoring it completely, while yet others are handicapped by having buildings which are sad examples of what healthy schools should not be. Sir George Newman urges local authorities, school medical officers, and teachers to give this subject their attention, for the teaching of hygiene is essentially a matter for conference and coöperation. Three things, he thinks, are needed. First, the recognition that health education is something wider than elementary physiology and should embrace the life of the citizen at home and at work; secondly, the acceptance of health education as a fundamental and integral part of the curriculum; and, thirdly, the working-out of courses adapted to the curriculum, type, and circumstances of each school. He is aware of the difficulties, but is aware also that ignorance on health matters spoils a substantial part of the country's educational effort. Many employers provide classes in hygiene for their new workers, as there has been no adequate teaching at the schools. The Board of Education in 1928 issued a "Handbook of Suggestions on Health Education," wherein principles and methods are set out. This book is not, however, receiving the use it deserves. The teachers have been instructed, a scheme has been drawn up; what appears to be lacking is the insistence by the local authority that the subject shall find a place in every school curriculum.

Schemes for treatment have now been in hand for about 20 years and are continuing to develop. Orthopædic and rheumatism centres and provision of ultra-violet light are among the recent additions, and the older clinics, for minor ailments, defective vision, teeth and tonsils, are improving steadily with experience. The chief difficulty is encountered in scattered rural areas, where all the medical agencies, public, private, and voluntary, must be linked up with the school medical service and the one clinic become the real health centre of the community. The principal figures for the year are as follows: eye and vision defects, 261,295; skin disease, 205,885; tonsils and adenoids, 177,807; ear defects, 46,087; deformities, 26,849; nervous diseases, 11,396; and heart disease, 5973. During the year 88,524 children under 15 died, 26 per cent. from respiratory disease, 24 per cent. from congenital conditions, 18 per cent. from infectious disease, 9 per cent. from diarrhœa and digestive conditions, and 5 per cent. from tuberculosis. There is therefore still a serious, though a much reduced, loss of child life. During school age the chief enemies are heart disease, pneumonia, diseases of the nervous and digestive systems, and accidents. The inability of the school medical service to prevent much of this disease is the measure of its failure. There does not seem to be a great change in the volume or character of illness among school-children during the last few years. This may be ascribed to several causes; first of all, many children who now swell the statistics would have been completely neglected a generation ago. Moreover, the average severity of illness is much less than it used to be, especially in such conditions as uncleanliness, skin disease, discharging ears, and enlarged tonsils. The X ray treatment of ringworm of the scalp is being more and more adopted, with excellent results, and is proving economical in the end. Gentian violet is proving satisfactory for impetigo. The report once more sets out the indications for tonsillectomy and urges that the operation should be regarded as a major one and provision made for keeping the child overnight.

---

[1] London: H.M. Stationery Office. 1930. Pp. 152. 2s.

The school medical officer has become more critical and his investigation more searching. Further, the reduction in infant mortality must mean that sicklier children now survive to school age, and if the care which nurtured these through infancy could be extended through the pre-school age there would be huge relief to the school medical service. An enormous amount has been done; there yet remains much to do.

DEEP X RAY THERAPY.

UP to the present time the published results of deep X ray therapy as practised in this country have been disappointingly meagre, wholly incommensurate in fact with the large number of cases treated by this method. There are, perhaps, two principal causes for this: first, a general dissatisfaction with the proportion of successes and a consequent unwillingness to publish until alterations in technique have been tried out; secondly, the conditions under which the work is usually carried on, which render difficult the keeping of records of a type which can be readily reduced to statistical form. It must be remembered that deep X ray workers contend with several disadvantages. The cases referred to them are usually advanced, often hopeless. Bed accommodation is so limited that nearly all cases are treated as out-patients. Pathological examinations of the growth can rarely be made. In short, research conditions usually do not obtain. We therefore welcome Dr. W. M. Levitt's admirable report of an investigation carried out over a period of six years under the direction of the St. Bartholomew's Hospital Cancer Research Committee. The results of the investigation are summarised in a review on p. 25. The report would in any case be welcome as a record of facts, but it is more than this. It is a very able and critical analysis of work carried out under research conditions by an authoritative committee and contains conclusions and suggestions of outstanding value. Sir Thomas Horder, as chairman of the Research Committee, states, in an introductory letter, that the report brings our knowledge upon the subject of the deep X ray therapy of cancer to a state of precision not hitherto attained in this country, and may well prove to be of great value as a standard in the matter for some little time to come. We can endorse this view, and we hope that the appearance of a work of this kind will stimulate other centres to publish their methods and the results hitherto attained. For such publications Dr. Levitt's report might serve as a model.

ASPIRIN POISONING.

IN Hungary aspirin poisoning seems to be the present fashion for suicides. The numbers of people treated for this condition at first-aid stations in Budapest during the three years 1927–29 were 230, 206, and 154, and Dr. J. Balazs, who gives these figures,[1] says that 752 such cases have been treated at his hospital there since 1923. Only four of these have died—a mortality of about ½ per cent.—although the average dose taken has been 300–450 grains. Aspirin being relatively insoluble, some of it usually remains in the drinking vessel, in the mouth, or in the gullet; furthermore, large quantities induce severe vomiting, which also diminishes the amount absorbed. In Balazs's series the minimal lethal dose seemed to be between 450 and 600 grains. Severe cases show the clinical features of an intense acidosis with Cheyne-Stokes respiration, small rapid pulse, and cold sweat; there is great prostration with thirst, vertigo, vomiting, and deafness. In fatal cases death occurs from heart failure, but in others the drug is eliminated fairly quickly and the patient recovers in a few days. The urine may contain albumin, large amounts of acetone, and sometimes red blood cells and casts. Characteristic post-mortem appearances are usually absent, though hæmorrhages in the viscera are described by some writers. In treatment, stomach wash-outs are important, and acidosis should be combated as far as possible. Intravenous injection of 4 per cent. sodium bicarbonate solution gave the best results in Balazs's cases, while insulin and glucose did not appear to be beneficial—which is hardly to be wondered at when the different ætiology of the acidosis of diabetes is remembered. Large quantities of fluids, either rectally or by mouth, are given to lessen dehydration and mitigate thirst. Only in the severest cases are cardiac stimulants required.

INTRACARDIAC THERAPY.

Dr. Albert Hyman has written a brief and useful paper on the present position of intracardiac therapy as a means of resuscitating patients whose hearts have ceased to beat.[1] He points out that the injection of drugs into the substance of the ventricular muscle is more likely to be effective than injection into the cavity of the heart, while injection into the pericardium is usually of no avail. The drug most commonly injected is epinephrine, but successful results have been reported from the use of ether, caffeine, camphor, digitalis, hypertonic salt solution, and many other substances. The diversity of these substances suggests that stimulation of the heart probably depends on the local irritant action of the injected drug rather than on any specific chemical properties. This hypothesis has been carried farther by some workers who have shown that the mere mechanical stimulation of the needle puncture may suffice to restart a heart which has stopped beating. The first beats of a resuscitated heart are extrasystoles, but in successful cases the normal sinus rhythm sooner or later supervenes. Several cases have been reported in which an initial success has been followed by sudden collapse with failure of the circulation. The development of ventricular fibrillation is the probable explanation of this calamity, and the known liability of the ventricle to fibrillate as the result of electrical stimulation under experimental conditions tends to corroborate this view. In order to overcome this difficulty it has been suggested that the injection should be made into the auricle rather than the ventricle. This is not difficult when a long curved needle is used, the site of puncture being the third intercostal space close to the right border of the sternum. Dr. Hyman says that successful results have been obtained in nine cases by this new technique, which he considers to be both safer and more certain than ventricular puncture.

It is clearly unreasonable to expect to resuscitate a patient whose death is attributable to acute or chronic heart disease. The various methods of resuscitation are applicable only in cases where the heart itself is apparently healthy, and stops under anæsthesia or as the result of surgical shock or collapse.

---

DIPHTHERIA TOXIN IN ERROR.

ANOTHER serious loss of life due to human error is reported from Medellin in the Republic of Colombia, South America. An account of the circumstances is given in the local press by the medical man who made the material. He had offered "anatoxine" (i.e., formalinised toxin or toxoid) free of charge to the local welfare centre. The first dose of 0·5 c.cm., and the second of 1·0 c.cm. a fortnight later, were given without incident to 50 children. The third dose of 1·5 c.cm. was to be given in November and a fresh bottle of the material was supplied by the maker. Apparently within 48 hours of the injection several of the children became gravely ill with acute vomiting. The doctor recounts that, on hearing this, he looked into his ice-chest and discovered that his bottles of toxin and of "anatoxine" had become interchanged in position, and that the bottle he had sent to the welfare clinic was not "anatoxine" but toxin. The newspaper stated that 15 children under the age of 5 had already died. No full clinical account, autopsy record, or report of the condition of the remaining children who had been inoculated was given. It will be recalled that in 1927 12 Russian children[1] were killed owing to the giving of toxin instead of prophylactic, and the disaster in Baden (Austria) was attributed by Grassberger[2] to a similar mistake. We had hoped that thereafter such elementary precautions as keeping toxin in a building separate from that in which the material for clinical use was handled—or at least in laboratories geographically separate—and an accountancy system whereby all toxin made was strictly controlled, would be everywhere observed. The loss of life in Medellin appears to be due to a human mistake, which was easily possible under the lamentable system of storing together toxin and prophylactic.

ALUMINIUM IN COOKERY.

ON another page our Berlin correspondent mentions a new inquiry into the supposed dangers of cooking food in aluminium pots and pans, and reports that it proved entirely reassuring. Some 17 years ago we ourselves made experiments[3] showing that "aluminium, as it is now made by reputable manufacturers, is a suitable material for cooking vessels," and again quite lately[4] we published analytical information leading to the conclusion that "even if small quantities are conveyed to the water or food, these are without influence on the health of the individual." If the bogy still shows signs of restlessness he may be referred to the more recent studies of C. Massatsch[5] and of K. Mackenzie.[6] Massatsch found that the attack of waters and foods on aluminium was, at ordinary temperatures and at 80° C., of the same order as on other base metals, and he came to the conclusion that this metal was without physiological action. Mackenzie, working at the Rowett Institute, Aberdeen, added up to 1 per cent. of aluminium in the form of aluminium sodium sulphate to the diet of freshly weaned pigs, and records that they seemed none the worse. There was a definite increase in the aluminium content of the liver and small intestine, and in one animal of the heart, but not in any case as much as 1 mg. per 100 g. of fresh material. Mackenzie concludes that the intake and excretion of aluminium in the pig are equal, within the limits of experimental error; that aluminium excretion is confined to the alimentary tract; that the absorption of aluminium from normal diets containing moderate amounts of available aluminium, as determined by the analysis of the organs, is small; that diversion of phosphates from the urine to the fæces does not occur on such diets; and that no harmful effect on general growth and metabolism results from administering comparatively large amounts of aluminium.

ALFRED MOND.

THE death of Lord Melchett at the age of 62 has withdrawn prematurely from public life one whose qualities and performances had won for him general esteem. In the world of commercial chemistry his influence was paramount, and it was his practical experience as a man of business which made him take masterly hold of the duties of Minister of Health. During his comparatively short period of office the fact, which he confirmed by his actions, that he belonged to no party, though necessarily associated nominally with the administration to which he owed his cabinet rank, was a mark in his favour with those who have to maintain the health of the country. Medical men, especially those whose official duty it is to administer the working of public health enactments, realise alike the virtues of conservatism and the necessity of change, sometimes of radical change, in response to the ever-varying factors in the incidence of disease. Every doctor is a socialist in the sense that he desires the members of society to have equal chances of health, but he must receive the doctrines of socialism with caution when he observes that the most obvious opportunity for each member of a community to receive an equal chance is when an epidemic falls upon that community. Lord Melchett worked valiantly for the common weal in many directions. His achievements in the rational developments of industry were reflected in his work at Whitehall, which is now bearing fruit; he was a generous giver in many judicious directions; and he was an open-handed supporter of the cause of his own people.

AVERTIN AND NITROUS OXIDE.

COMBINATIONS of anæsthetics are at the present time "in the melting-pot." Almost every week brings some new and warmly recommended association of drugs. The chief aim now appears to be to discover some means whereby nitrous oxide can be rendered effective for major surgery without the aid of ether or chloroform. For this purpose H. Flörcken[1] has been using avertin, and is well satisfied with his results. The operations performed under anæsthesia due to rectal avertin followed by gas-and-oxygen inhalation included 80 gall-bladder cases, 52 resections of stomach, prostatectomies, and thyroidectomies for Graves's disease. We understand that some anæsthetists in this country, too, have been using this same combination of drugs with satisfaction. Very often the results have left little room for improvement.

A POST-GRADUATE COURSE

MOTIVES AND MECHANISMS OF THE MIND.

I.—CLEARING THE GROUND.[*]

INTRODUCTORY.

I HAVE not attempted to quote authorities in these lectures for several reasons. The task would be beyond me to do adequately, and would involve a loss of unity and simplicity which I have tried to maintain by presenting an individual point of view, based principally on clinical experience. The advantages and disadvantages of this method are obvious, but I feel that these lectures should be prefaced with some acknowledgement and apology to those authors whose work may have suffered in my attempt to simplify what must always remain a most difficult subject. Although each lecture in itself may seem to do its subject less than justice, I have aimed rather at presenting them to form a whole, provocative of thought and introductory to further study, rather than to define any origin and final system of psychology. I would also like to express my thanks to Dr. Henry Yellowlees, of the Department of Psychological Medicine, St. Thomas's Hospital, and to Dr. Crichton Miller, honorary director of the Tavistock-square Clinic, for permission to refer to cases.

Two Viewpoints.

What do we mean by "nerves"? It is probable that the diagnosis which the doctor most commonly makes, at least in the privacy of his own mind, is that of "nerves." It is a word which is most useful to him, covering, as it does, a large group of cases which it is difficult to classify in any other way. It is also very popular with patients themselves, whatever their social rank may be. There is no doubt that this label has a definite euphemistic value, and this accounts to a great extent for its popularity and usefulness. To tell a patient that he (or she) is suffering from mental disorder would probably cause an increase in his anxiety, if it did not send him to another doctor who would be considerate enough to say that it was "only nerves."

In taking a patient's history it is a common experience, in reply to such a question as "Have you ever had any mental trouble before?" for the patient to say, "No, doctor, but my nerves have been bad." Further questioning in one case brought to light that the patient had actually been under certificate at a mental hospital for six and a half years suffering, in his opinion, from "nerves"! It is not hard to understand the value to the patient and the patient's relatives of the use of this vague term. Rightly or wrongly, mental disorder is associated with disgrace, but there is no disgrace in having suffered from "nerves"; if anything, it is something of which to be a little proud. "She was always a highly strung child" conveys a fond mother's pride in her daughter's peculiarity.

Of late years another term has crept in, possessing the same useful purpose, but expressed in a rather more dignified manner. There is a tendency amongst doctors to feel that when they have described a patient as suffering from "neurasthenia" they have added to their scientific comprehension of the patient's disorder. "Neurasthenia" is applied in the same vague and general way, and with the same aim in view, of satisfying both doctor and patient without damaging the prestige of either. But neurasthenia has a definite and limited meaning, and if used accordingly it should only be applied to something under 1 per cent. of those innumerable patients suffering from "nerves" who consult the general practitioner. Neurasthenia refers to a condition of heightened fatiguability, and is a comparatively rare disorder, in spite of the frequency with which the term is used. Doctors wishing to distinguish between the real disorder to which the term applies and the general condition for which the term is used, but to which it does not apply, sometimes speak of "true neurasthenia." It is not unusual, however, to find that true neurasthenia means no more than neurasthenia, as a general group label for all mental disorder, and that a patient sent up for a consultation with the suggested diagnosis of "true neurasthenia" may have, in fact, any other kind of mental disorder, such as dementia præcox or manic-depressive insanity.

THE NEUROPHYSICAL POINT OF VIEW.

Both in the out-patient department of a general hospital and in general practice it is the custom to classify patients into "organic" and "functional," and it is the tendency to dismiss the latter as of comparative unimportance, although the probability is that they represent a large proportion of the cases applying for treatment. From the point of view of social economy it cannot be sufficiently emphasised that so-called "functional" disorder is responsible for an incalculable amount of social inefficiency and domestic infelicity.

Whether the disorder be called "functional nervous disorder," "neurasthenia," or simply "nerves," the tendency is either to ignore it as not being worthy of medical interest or to apply certain time-worn and not always suitable methods of treatment.

In general there would seem to be uncertainty in the doctor's mind as to whether the symptoms are due to some vague moral disorder on the part of the patient or to an equally vague disturbance of the nervous system. The treatment usually falls under one of the following four headings:—

(*a*) The *exhortatory method.*—This is usually the first method applied by relatives, and assumes that the patient is in some way blameworthy for not doing what he should, and only needs talking to in the right way to be cured.

The advice given too often by doctors, as well as relatives, is that the patient only needs to "pull himself together," that "there is nothing the matter with him," and that "it is all only imagination." After this advice has been repeated a few times it tends to become more caustic and more punitive. The relatives are perhaps told that all the patient requires is discipline, to settle down to some really hard work, and to be made to suffer hardship. This method of treatment begins with a plain assumption of benevolent omnipotence. It usually ends with an effective attempt not so much to cure as to dismiss both patient and symptoms by the prescription of a sea voyage or an open-air life, to be spent in digging the land—preferably in a far-off colony of the Empire, where conditions are such as to test the physical and moral adaptability of the strongest constitution.

(*b*) *Medical.*—Up to recent years the drugs available for cases of nerves were mainly either sedatives or tonics. More recently, since endocrinology has come to the fore, a great choice of remedies of this type has been put into the hands of the doctor, and exploited as a rule with an enthusiasm in inverse proportion to their therapeutic reliability. In general, where the cause of a disorder is unknown, two tendencies will be noticed. The first is an assumption that one particular treatment is a panacea, the second is a tendency to apply a multiplicity of remedies. The panacea is an example of wish-fulfilment. It is an over-compensation for a "feeling of inferiority" towards the disorder to cover the fact that we do not like to admit to ourselves that we really do not know much about it. Where there are many alternative remedies there is usually the same underlying uncertainty, and the degree of enthusiasm with which they are applied is not to be taken as a true measure of their therapeutic activity. The value of medical remedies in disorders of the nervous-emotional system must always be extremely doubtful, owing to the difficulty of determining to what extent they have been actually causative in any ameliorative changes which the disorder may undergo.

---

[*] A course of 12 lectures delivered under the auspices of the Tavistock Clinic, Tavistock-square, by Dr. E. Graham Howe during the autumn session of 1930. Lecture II. will appear next week.

It must always be borne in mind that one of the great values of medicine is as a vehicle of suggestion. To what extent the action of a medicine is due to suggestion, and to what extent it is due to pharmacology, must always be open to doubt. There are many patients of the same type as the one who said, "My blood is such a pale colour, doctor. Will you give me some of that red medicine to make it stronger?" She was given the red medicine, which incidentally contained iron and arsenic, but in all probability its beneficial effect, if any, was due to her faith in the colour of it, rather than to its pharmacological properties.

(c) *Rest and diet.*—The most extreme example of this method, used as a panacea, was originated by Dr. Weir Mitchell in America. When faithfully carried out it consists of 8 to 12 weeks' absolute confinement to bed and seclusion from relatives. The patient is forbidden to make any movement of his own accord, and if he wishes to turn over in bed it must be done for him by the nurse. At the same time that his exercise is reduced to a minimum, his intake of nourishment is increased to a maximum. It might reasonably be anticipated that the balance of energy in the nervous "bank" would, by this method, be rapidly increased. Its value, however, is limited owing to the patient's inability to do nothing without worrying, and in practice it is necessarily modified. It is another example of a method which has a limited usefulness in certain cases, but by being carried to extremes as a panacea it is liable to be used in many cases where it is not suitable.

(d) *Final or dismissive.*—The last shot in the locker of a physician who knows only the "neurophysical" method of approach to his patient's disorder is the too often repeated prescription of a sea voyage. It would be interesting, if it were possible, to obtain statistics to indicate successes and failures of this method; the number who have never returned and the number who have returned no better than when they departed. Whatever may be its advantages to the patient, it is easy to appreciate its usefulness to both doctor and relatives. The patient, whether he suffers from "nerves" or "neurasthenia," can be a great trial to doctor and relatives alike, and the prescription of a sea voyage is at least beneficial to those who are temporarily set free from the responsibility of his care. It is no doubt occasionally beneficial to patients whose environment has become too difficult for them, and provides a change in the early stages of paranoia which may delay the progress of the disease. In the majority of cases, however, it is both unnecessary and unsuitable, besides being usually economically impossible.

"OMNIPOTENT" METHODS: SUGGESTION AND PERSUASION.

Of recent years other lines of more definitely psychological treatment, usually in the hands of specialists, have come to the fore. These aim at a cure of the patient's disorders by methods either of repeated persuasion or hypnosis. Although these methods show an advance in many cases on those already mentioned, they share with them the disadvantage of being unscientific. Like all unscientific methods, they tend to be invested with an atmosphere of omnipotence or God-like magic, which attempts to exorcise the patient's disability without having first discovered the cause of it.

The Development of Psychopathology.

The greatest advance in general medicine has always come through ætiological research, the cause of the disorder being thoroughly investigated and understood before treatment is prescribed. Such an advance as the use of antitoxin in diphtheria was due to the discovery of the causative bacillus and its activities in the tissues. Previously treatment had only been on symptomatic lines, aiming at relieving such general conditions as temperature and the local affection of the throat. When the cause of the disorder was discovered, it became possible to treat the cause, and the importance of the symptoms became secondary. The ætiological and pathological approach towards patients, their symptoms and their problems, is the bed rock of medicine as a science and the test of its progress. It is only of recent years, since the investigations of psychological material by Dr. Sigmund Freud, of Vienna, and his followers all over the world, that psychology has fallen into line with general medicine and deserved the prestige of any scientific status.

The fact that psychology has at last developed a more scientific method of approach to the problem of mental disorders does not, however, necessarily mean that it should be included amongst the sciences. It is probable that there will always be more in psychology than can strictly be described as "science," but the same may be said of medicine itself.

ANALYTICAL PSYCHOLOGY.

Analytical psychology is the term used to describe this method of tracing back from the symptom to the cause. Whether carried out according to the specific technique of Dr. Freud or according to the modified methods of Dr. Jung or Dr. Adler or their followers, it aims at establishing a psychopathology which may enable us to understand disorders in psychological medicine in the same way that a knowledge of pathology is the basis of our work in general medicine. When we understand the psychology and pathology of the conditions that we are asked to treat, we are in a position to apply a general scientific technique, and not before. It is true that there are many schools of psychology which, although they hold much in common, differ at many points. Psychology as a science is still in its infancy, and the scope it offers for research is as deep as human nature itself. Differences must therefore be welcomed and doubts tolerated, for it must be many years before any degree of finality can be attained. It is sufficient to mark a new era that our understanding of, and control over, mental disorder is at last, and for the first time, being built upon a scientific foundation.

Psychopathology and psychotherapy being both as yet so young, it is unfortunate that any school of psychological research should be abusive of the methods adopted and recommended by those who have adopted another point of view. Only a wide vision, with much mutual toleration and willing team-work, will solve the problems involved in the subtle interactions of mind and body, heredity and environment. But at present the neurologists can see little that is good in the methods adopted by the analysts, and even the latter are liable to be as intolerant of divergencies of opinion amongst themselves. This tendency to be exclusive and intolerant of different opinions is inimical to progress, but it is characteristic of human nature and as such it requires to be understood, rather than regretted or ignored. The cause of it will probably become more clear in the course of the pages that follow. Every progressive movement in history has had to be born and developed against opposition and, if on the right lines, it has thrived by the experience it has gained in the struggle. It is true that some of the criticism which has been levelled against modern psychology is justified, and should, therefore, be welcomed as necessary for its development as a progressive science. But at least modern psychology demands and deserves critical and sympathetic consideration. It would be equally unwise to accept or reject it wholesale, if indeed any unified conception of it could be discovered at the present time. The tendency with a single gesture to divide the world into sheep and goats, right and left, right and wrong, is a common error latent in the immaturity of human nature. We praise wholeheartedly and blame with equal abundance, until we learn to discriminate more subtly in our criticisms. To condemn all or praise all is a sign of unbalanced immaturity. Modern psychology may have made some mistakes; but it contains a nucleus of truth which is of unparalleled importance for the human race, and it can no longer be ignored.

Cases Suitably Treated by "Neurophysical" Methods.

The treatment which any case will receive is liable to depend on whether it be treated by a neurologist or a psychologist. Each is prone to treat the same case exclusively according to his own methods. From the point of view of the doctor it is of great importance to recognise those cases which are suitable for treatment by the simpler methods of encouragement, rest, and appropriate medicine. There are many cases which do not require the psychological approach because their psychopathology is not of primary importance. It would be a very grave error, however, to believe that the psychological side is unimportant in any of the following types. In any one the psychological factor *may be* of primary importance, but the headings are suggested as including a great many cases with which the general practitioner can deal unaided. The classification of those disorders which can arise without the need for investigating the psychopathology may be stated as follows: (*a*) fatigue states, (*b*) toxæmias, (*c*) endocrine disorders, (*d*) disorders due to shock, (*e*) disorders due to environment.

FATIGUE STATES.

Under the strain of economic conditions and the innumerable stresses of everyday life it is inevitable that fatigue should play a large part in the development of common mental disorders. It is only necessary to consider the way in which symptoms of disorder develop in a tired child. The outbursts of temper, instability of character, and signs of physical fatigue are the inevitable consequences of a nervous system which has been asked to perform more than it was able to fulfil. Treatment for the tired child comes normally at the end of the day with rest and sleep, and the next day finds the child ready to resume its normal life refreshed and re-established in its adjustment towards its environment. Only after the process of undue exhaustion is repeated and prolonged is the child's capacity for recuperation likely to be insufficient. If we are wise, we do not treat the tired child with a long exhortation on the psychological causes and social effects of its disorders. We simply put the child to bed, and time and nature do the rest. This is the simplest form of what is meant by neurophysical treatment.

It is a common fallacy to tell a child that he or she is being naughty, for the same reason that the doctor or relative is inclined to tell the patient that he or she is being naughty or lazy or stupid. There is no small measure of satisfaction to be found for any one of us in criticising one another. It adds to our sense of power and well-being, but the fact remains that the child is not naughty, but tired, and that rest will do more to put things right than blame.

The case of Mrs. A. may be taken as typical of many others of similar causation which occur in general practice. She was seen as an out-patient in the department of psychological medicine at St. Thomas's Hospital.

CASE A.—Female, married, aged 30, five children (eldest 9, youngest 15 months).

Complained of very severe stammering, occasionally complete loss of voice, headaches, choking feeling in the throat, nervousness, extreme irritability with the children.

Physical signs.—Thyroid prominent, slight exophthalmos, reflexes exaggerated, pulse 100, tremor of the hands, teeth bad.

History.—Nothing outstanding of importance in childhood. She was said to have been anæmic at puberty, and to have been always of an excitable disposition. She was married at 20. During her married life her husband had been frequently out of work, and had never earned more than £3 a week. Living accommodation had never been more than two or three rooms, and the children had had many illnesses. She stated that she had never been free from worry about the children. There had always been financial stringency and she had never, during her married life, been away for a holiday. During the last four weeks the baby had been suffering from bronchitis. The doctor had advised the use of a bronchitis kettle, which had been devised by inserting a piece of lead piping into a broken kettle. The water had boiled away, and the weight of the lead piping had caused the kettle to upset over the baby, burning it severely, and it had been taken to hospital a week before. It had been very dangerously ill, and the mother had been going to and fro several times a day to the hospital. The shock of this accident had brought on the stammering.

Diagnosis.—Exhaustion and shock. Psychopathology is relatively unimportant. Anxiety state in a hysterical subject.

Treatment.—The patient was first sent away for a fortnight's convalescence at the seaside. She came back much improved. Her stammering had disappeared, but recurred with the renewal of responsibility and anxiety for the children. It disappeared again when she settled down at home. Her teeth were in a very bad condition, and a dental X ray showed much pyorrhœa and some formation of apical abscesses. She was referred to the dentist, who extracted 16 at a single sitting, the remainder a week later. As a result she had a period of insomnia and complained of severe pains in the head, and a general increase in her symptoms. Four months later, having been seen at intervals of a few weeks, the patient reported practically well. Her pulse was 70. There was no exophthalmos or thyroid prominence, no stammering or headaches, and she was very cheerful. She had to continue to live in very undesirable and inconvenient quarters, which materially delayed her complete recovery.

TOXÆMIAS.

The subject of fatigue states was introduced by a consideration of the consequences of fatigue in children, and it is helpful to begin our study of toxæmias from the same point of view. Very little experience of children is sufficient to prove the importance to the child of a daily motion of the bowels. If two or three days have gone by without elimination of the waste products of digestion, the child will become lazy, ill-tempered, and apparently out-of-sorts. A dose of some mild purgative will do more to re-establish the child's equilibrium than any measure of exhortation.

It is a common experience to contribute our own disordered emotional states to a "cholæmia" which we do not hesitate to treat with a mild dose of calomel, expecting to view the problems of our lives from a more optimistic angle on the following day. What we do not realise, however, is that many of our patients are constantly in this condition and, not having the knowledge to apply such a simple remedy, the disordered state of their alimentary function has been allowed to go beyond such easy repair. It would seem, therefore, to be inevitable that toxæmia from the bowels should be a frequent cause of disordered metabolic function in a large number of patients.

Toxæmia is a potent depressor of metabolism and most commonly occurs from one or other of the following sources: (*a*) bowels, (*b*) teeth, (*c*) tonsils, (*d*) sinuses.

The following case (another hospital out-patient) appeared to be one in which a chronic frontal sinus infection was mainly responsible for the patient's condition.

CASE B.—Male, married, two children. Aged 49.

Complained of depression, lack of concentration, complete inability to do any work. Frontal headache, worse in mornings and present on waking.

Signs.—The patient was obviously depressed, but there was no delay or dullness in his answers to questions, and he did not appear to be emotionally retarded.

History.—He was brought to hospital because he had disappeared one evening after having been very depressed, and had been found by friends meditating suicide on a canal bank. He had had certain business anxieties, but not sufficient in themselves to be overwhelming. He had not had any previous attack of depression. He was happily married, but had always taken life seriously and was of a reserved, quiet disposition.

Treatment.—Inquiry elicited the history of attacks of nasal catarrh and postnasal discharge. He was referred to the nose and throat department, who diagnosed chronic frontal sinusitis. This was treated; and a month later he was able to resume work, having discussed the whole matter of his depression very sensibly.

At every point the general practitioner is faced with the temptation to apply a single remedy as a panacea. A word of warning is particularly applicable on the subject of toxæmia.

There is no doubt that certain cases do benefit by extraction of teeth. There is equally no doubt, however, that it is a great deal easier to extract teeth than it is to put them back again, and that no artificial tooth is quite as good as a real one. The best safeguard is a competent dental X ray, confirmed by the dentist's clinical examination, and a conservative attitude on the part of the physician. The effects of toxæmia may be very varied. In general, we may expect to find symptoms of metabolic depression, with a tendency to stasis and low blood pressure, but the emotional symptoms which may occur depend upon the emotional constitution of the patient. In brief, the chain of the patient's psychophysical constitution will be liable to break at its weakest link, and the symptoms, whether physical or emotional, will be those to which the patient has in the past been most liable to succumb.

ENDOCRINE DISORDERS.

Endocrinology is still in its infancy, but the disorders which most commonly come under the notice of the general practitioner are those associated with under- or over-activity of the thyroid gland. We are faced with the question as to which may be primary—the endocrine disorder or the emotional. In the case of Mrs. A., already mentioned, her anxiety was associated with some enlargement of the thyroid and a rapid pulse, three of the four cardinal symptoms of exophthalmic goitre. When the anxiety and exhaustion were removed, the function of the thyroid became normal again and may be assumed, therefore, to have been secondary to her emotional condition.

Some cases of anxiety, with symptoms of an over-active thyroid, are found to respond satisfactorily to administration of iodine—e.g., ♏1 of the French tincture t.d.s. in milk. In others, it may be necessary to discover and remove the source of anxiety, frequently a sexual factor.

Another type of thyroid dysfunction is that which occurs when the thyroid is under-active, of which the following is an illustrative case.

CASE C.—Female, married, aged 40, one child aged 12.

Complained of depression, tiredness, head pains, swimming feelings. "I don't mind if I live or die sometimes." Fear of going out and crossing roads. Periods reduced in amount: duration two days. Constipation. On inquiry she stated that she felt the cold dreadfully, and was putting on weight.

Signs.—Skin very dry and thick, pulse 84, temperature 97·8, dull and lethargic.

Treatment.—Began with gr. ½ of thyroid twice a day, increased after a fortnight to three times a day. After four weeks she said: "I feel very much freer in the mind and body. I used to feel so depressed. I have been out a lot more, and do not feel so tired." The thyroid was gradually increased up to a maximum of gr. 2 siccum three times a day, omitted during her periods. This was beyond the limit of her tolerance, and she lost 4 lb. in weight in a fortnight and her pulse was found to be 130. The thyroid was reduced to gr. 1 three times a day, which was maintained without symptoms of intolerance, and she stated that she could not possibly do without it. At the end of another month her periods were normal, pulse normal, skin softer and moister. She stated that she was practically free from all the symptoms of which she had complained three months before. She was bright and cheerful, and said that her friends remarked that she was like a different woman.

DISORDERS DUE TO SHOCK.

Certain severe nervous shocks cause instability and give rise to inadequate or pathological behaviour. Shocks of one kind or another are inevitable in every lifetime, and vary in degree from such an unusual experience as a severe thunderstorm to a child, a motor accident, or the shock of a sudden death. An example of the first occurred to a child of two years old. It was not the first thunderstorm the child had experienced, but it was exceptionally severe. The child had gone to sleep and was awakened suddenly by a very severe clap of thunder, by which she was extremely frightened. Succeeding claps of thunder, although not so severe, produced the same response of fear until the storm was over. She then had recurrent violent attacks of vomiting, which lasted for about an hour, and it was a day or so before her gastric condition became normal. This would seem to be a case in which a nervous shock produced a nervous disability chiefly gastric in its symptoms.

Up to this point it is not possible to say that there had been any psychopathology in the production of the child's symptoms. But what would happen with successive thunderstorms? The emotional response of fear at the sound of thunder had been aroused, and the child had been comforted by the mother. A chain of events had been established: thunder, fear, crying, and mother. It would be only natural in the event of another similar fear stimulus for the child to respond in the same way and flee to the mother again for comfort and protection. From this point the need for the mother has been introduced and, with her, psychopathology. If the thunder becomes a means to gratify the child's wish for its mother, the thunderstorm, although still feared, becomes desired and made use of, as a means of gratifying the wish of the child for the mother. To use Prof. Pavlov's terminology, it has become a "conditioned reflex." If this occurs, a psychopathology has been produced and the response will be exaggerated as a means to produce the desired end—i.e., maternal love and protection.

Accidents are nervous shocks and in themselves are independent of psychopathology. The nervous shock alone will respond to treatment by rest, time, and re-education. If a correct adaptation is made, the injured person should be able to run the risk again without expecting to have a repetition of his previous experience and without exaggerated fear. His experience will probably have instilled added caution, but nothing more. It is common, however, for such an accident to produce symptoms of psychopathology beyond the nervous shock. The integrative nervous-emotional unit is most liable to break down at the weakest link.

CASE D.—Male, married, aged 57. Four children.

Complained of depression, self-criticism, lack of concentration. *Duration six months.*

History.—He had always been of a nervous temperament, over-anxious about himself, and making the most of illnesses, usually more or less imaginary. He had been ambitious and embarked on business adventures until his courage failed, when he would do his best to get out of them as quickly as possible. In private life he found ambition and security in social and committee work, in which he was something of a tyrant. His wife was far more dominant in the family than himself. He met with an accident while being driven in a car, and after it he complained of shock. He was not injured and the accident was only a minor one. He returned to work the following day, but was more anxious, and complained of loss of concentration. He became worse, and after a week, being quite unable to work at all, he retired to bed. He became depressed, and spent his time worrying over trivialities and exaggerating all the failures in his life which he could remember. His integration had been destroyed by the shock of the accident, and he now became a problem in psychopathology.

This case serves to illustrate the way in which the cause of the symptoms may be primarily organic, but may give rise later to more important psychological conditions.

DISORDERS DUE TO ENVIRONMENT.

Environment may be emotional or physical. There are many cases in which disorders will clear up if the patient is removed from home surroundings. For example, where father and son are making the worst of each other. It seems to be almost a biological necessity that sons should look at life from a different angle from their fathers, and that fathers should regard their sons' developing ideas with some measure of disapproval. It too often happens that this more or less inevitable biological friction is carried to such a point as to give rise to symptoms of minor emotional disorders. Removal of the son to a more sympathetic environment may help to re-establish harmony. Sometimes it is the father who is at fault, sometimes the mother, and sometimes both. The problem of environment is always more important where the patient is youthful.

Physical environment is sometimes responsible quite apart from emotional difficulties. A highly strung, intelligent well-educated, and ambitious man of 32 was earning £2 12*s.* a week as a mechanic in a mass production workshop, where he was surrounded for eight hours a day with clanging machinery. He developed insomnia, irritability, nervousness, and depression which cleared up after a month's holiday, and he was advised to try to find a job more suited to his temperament. Similarly, young girls who have to stand for long hours in a close atmosphere are very liable to develop symptoms of emotional disorder.

Cases which Require Psychological Treatment.

INSOMNIA.

The symptom of insomnia is an ever-present responsibility to the general practitioner. Are we here dealing with a neurological problem or a psychological one? If it is only failure of the neural integration we are right in our prescription of sedatives, with perhaps some assurance as to the relative unimportance and curability of the condition. There are cases of insomnia which clear up under such treatment, but there are others which are extremely intractable when treated only from the neurological or organic standpoint. These cases usually present underlying problems in psychopathology which can only be understood and adequately dealt with from the psychological point of view. In such cases insomnia becomes useful to the patient and the symptom is a purposive one, even though it may be quite dissociated from his everyday conscious behaviour.

Two cases may briefly be taken in illustration:—

CASE E.—Female, married, aged 52, no children.

Complained of intractable insomnia.

History.—Her father had been a doctor, to whom as a child she had been extremely devoted. He had been in the habit of stroking her forehead before she went to sleep, and she remembered lying awake in order that her consciousness of this pleasant experience might be prolonged. She married late in life, and her attitude towards her husband was never satisfactory. She said he had never understood her, and she spent a great deal of his money in seeking doctors who might be better able to do so. She had recurring attacks of insomnia associated with anxiety. She went to an hypnotist who treated her by placing his hand on her forehead and speaking to her in a way which reminded her of her father. The treatment was far from being successful, but produced instead an attack of acute anxiety and depression, with increase of insomnia. The cause was discovered under analysis. The insomnia was a means to an end, a way to centre upon herself the doctor's attention, and the doctor was a substitute for her father.

The symptom was purposive, and was therefore not to be cured by ordinary medical methods. The more treatment of that kind that she had the more persistent her symptom became. It may be asked, "Why, if insomnia was the means, and father-doctor the desired end, was the symptom not appeased when she was the centre of the doctor's attention?" The end, although wished for, was an intolerable one, owing to the emotional conflict involved. This will be made more plain in later chapters.

CASE F.—Male, unmarried, a clergyman, aged 35.

Complained of intractable insomnia of ten years' duration. His physical appearance was perfectly healthy, and belied his statement that he never slept.

History.—His father was a very dominant personality, himself a clergyman, who had decided that all his sons were to follow in his footsteps. He had also decided that they were to be a great credit to the profession which he had chosen for them, and do surpassingly well in their preliminary examinations. The patient had had doubts as to any wish on his part to enter the Church, but his father had instilled into him the high calling of the family and his responsibility in the matter as a spiritual leader. The patient had with great difficulty passed his examinations, and found it very difficult to fulfil his father's ambition. He had an inevitable sense of failure, and an intense fear of being unable to do *what was expected of him. The insomnia began after an* operation for tonsillectomy, in which he expected to die under the anæsthetic. His horror of sleep was associated with his horror of anæsthesia, a horror of "letting himself go" or of losing consciousness. His attitude towards life was apprehensive, clutching on to straws that might aid his self-approval. In his parish duties he became subject to attacks of acute anxiety with trembling, sweating, and intense emotional discomfort. He could not sleep, so he could not be expected to do his work while suffering such agonies of insomnia, and it had to be given up.

His insomnia provided an excuse for his failure; it was an unfailing source of self-pity for his martyrdom, it was an escape from his responsibilities and a subtle revenge against his father. No wonder it was intractable!

THE NERVOUS TEMPERAMENT.

A similar problem to that which is presented by insomnia is seen in such cases as enuresis and stammering. Are these to be regarded as belonging, in respect to treatment, to the neurologist or the psychologist? The psychologist will say that enuresis has a definite value to a child in that there is a certain element of *gratification derived from bed-wetting. It is a way of* making a fuss, of calling attention, and of getting into the limelight of mother or nurse. It is an example of a "conditioned reflex" in which bed-wetting has become associated with the desired object, the mother.

In the same way the psychologist will say that stammering has a defensive function. It is a means of setting the patient on one side, of separating him from the world and his problem. It is quite true that both these symptoms have a purposive value, but is not the neurologist right in considering that they are also the sign of primary failure of integration in the synthesis of the nervous-emotional system?

Integration of the nervous system normally occurs with growth and development. For example, it is the integration of the nervous system which enables a baby to walk and later to develop the finer movements of the hands and to speak. Delay or failure in this capacity for nervous integration is a sign of a primary hereditary defect, quite independent of any psychological usefulness which may be derived from it later.

This brings us to a consideration of the nervous temperament, and of the individual who is so often described as being "highly strung." The disabilities of the nervous temperament may be divided into three:—

(*a*) *Failure of integration.*—The nervous system—physical, emotional, and mental—which should work together as a whole, as a single unit in harmony, fails to do so. There is conflict instead of team-work, disunity instead of unity.

(*b*) *Over-sensitiveness to stimulus, especially fear.*—This is the thin-skinned type who feel more acutely and are more subject to disturbances of one kind or another.

(*c*) *Inadequate or indefinite response to stimulus.*—The *nervous temperament* finds *difficulty in responding* adequately or definitely to a stimulus. Either there may be a lack of primary dynamism or an uncertainty as to the course of action which the occasion demands.

It is this combination of a failure of integration, increased excitability and inability to make an adequate response in behaviour, which makes the life of the possessor of the nervous temperament such a problem and gives the type a tendency towards instability.

FALSE ADAPTATION.

Life is therefore more difficult to the possessor of the nervous temperament, and it is often through symptom formation that adjustment is made to the challenge of reality. Symptoms are developed automatically and unconsciously to solve those problems where consciousness has failed. The symptoms are therefore purposive, and only when viewed from that point of view will therapeutic measures be successful.

CASE G.—Female, unmarried, aged 37.

Complained of uncontrollable habit spasm, her head jerking back and her arms jerking upwards in certain circumstances.

History.—For 20 years she had been on the same stool, at the same typewriter, in the same small office, under the same employer, in an ironmonger's shop. Her symptom developed at the typewriter, and she was quite unable to continue with her work. Her head jerked back, her arms jerked upwards, as if something horrified her from which she was trying to get away.

The interpretation of the disorder is one which aptly described her emotional attitude towards her work. Her life had no other outlet, and she longed for change and freedom, but the desire was completely unsatisfied in the drabness of her oft-repeated task. Where her mind had refused to make the necessary change in her condition, her nervous system had come to her aid and gratified her strongest wish to be free, but, as is always the case with such automatic actions, her freedom was dearly purchased at the expense of a symptom.

Summary.

1. There is a right and a wrong way of treating any disorder, whether physical, "nervous," or mental. The wrong way is symptomatically, the right way is ætiologically, trying to discover and remedy the "*cause.*"

2. In problems of mental disorder there are two different directions in which the cause may be sought—it may be *physical*, e.g., due to toxæmia or endocrine disorders, or it may be *emotional*. Both physical and emotional factors may be involved.

3. If a person is ill enough to be told to "pull himself together" he is ill enough to see a doctor, if he be the right kind of doctor. A patient suffering from "nerves" must be regarded in just the same *ætiological* way as a patient suffering from any form of organic disorder, but usually requires a great deal more patience.

4. Where the illness appears to be due to environmental factors, or to such physical conditions as endocrine disturbance or toxæmia, it is necessary first of all to treat such causes as can be found.

5. Where there is no apparent cause, a tactful and careful history of the sex life should be undertaken. Education on common-sense lines and instruction in elementary sexual hygiene—for example, of husband and wife in a case of anxiety over pregnancy or the practice of coitus interruptus—may do much to remove intractable symptoms, both emotional and physical.

6. Where all else fails, the case should be referred to a psychological expert who has more time and knowledge to devote to such cases than the busy practitioner can be expected to possess. It is better to let him find the cause of the trouble if he can, than for the practitioner to adopt heroic surgical methods or advocate dismissive sea voyages.

comes a paper by H. R. Müller and A. Stender,[3] in which an acute paraplegia whose causation entirely escaped detection during life proved to be due to *S. mansoni*, evidently acquired in South America with initial symptoms passing as gonorrhœa. The characteristic eggs formed centres for numerous pseudotubercles studding part of the dorsal region of the spinal cord. It is noteworthy that the Indian writers for the liver, and the German ones for the cord, both use the term pseudotubercles. Had a commercial antigen been available, it is probable, in view of the early symptoms, that a complement-fixation test would have been positive in serum, and it is possible, in view of the condition found after death and the analogy with hydatid infection, that it would have been positive in the cerebro-spinal fluid. The puzzled clinicians would have had a lead to treatment, and the patient might have had some hope of betterment. Watchfulness in such cases is the more needful, since a cerebro-spinal habitat has now been reported for all the three schistosome species which infest man.

The effects of treatment on goats were interesting. The proportion of male to female worms in untreated animals was 2 to 1, in those treated with emetine 4·3 to 1, and with tartar emetic 6·2 to 1. In a treated goat there were found 406 days after infection 25 male worms, no females, and non-viable eggs in the intestinal wall; yet the animal gave a strong positive complement-fixation reaction when tested two days before death. Persisting infection was, then, detected in an animal no longer infective, a refinement of diagnosis nevertheless important for the individual patient. The Bombay workers are, however, disposed to think that a positive reaction may be maintained by absorption of products from disintegrating flukes after all are dead, an important practical point which will be settled only when knowledge is greater.

Aspects of Immunity.

The disappearance of schistosomes under treatment leads naturally to certain aspects of immunity, using the word in a wide sense. Infection with male schistosomes only has been attributed to infection by cercariæ from a single mollusc which has been infected by a single miracidium, the last having its sex already fixed. Another hypothesis suggests that it is with the mollusc that determination of sex lies, holding that at certain seasons some factor renders impossible the survival of female cercariæ. In the Bombay work worms found in guinea-pigs were, with good reason, believed to be exclusively male. This host was then the dominant factor in determining the sex, since the material used was a fair sample of a mixed collection from several snails, material which produced normal sex proportions when used to infect goats. Though, then, the sex may be implicit in the miracidium, the host, intermediate, definitive or both, seems finally to determine whether only the sturdier male shall survive, seems to possess a specific or perhaps individual immunity to the female fluke. There is, too, an organ immunity becoming, as has been noted, stronger as the worms age. This can hardly be due merely to clotting of blood round the flukes—as is suggested from Bombay—for this occurrence is in no way restricted to unusual worm habitats. Rather must it be looked on as a special instance of a general principle. Every animal has a restricted range in the world, and every parasite is equally restricted within its small world—its host. The restriction of free living animals is in no way due to the presence of specific chemical anticonditions in other parts of the world, but to the absence of specific proconditions in those in which they prosper. There is nothing to suggest that this general principle does not hold for animal parasites, including schistosomes; or that the antibodies which appear in the host are in any way inimical to the parasites, and do not merely serve to neutralise their toxins, for, as has been noted, these antibodies remain in high titre at a time when further decrease of the fluke-population is held to have ceased. The Bombay work affords, too, evidence that some immunity in the ordinary sense can be acquired, that one parasitic invasion confers some protection against a second. In a first infection in the monkey, *Macacus sinicus*, schistosomulæ reached a certain stage of development before dying. An attempted reinfection three months after a first one resulted in almost complete failure. Moreover, M. Ozawa[4] found that, of five dogs infected with *S. japonicum*, cured by stibnal and reinfected, one proved altogether refractory to reinfection, and in the others symptoms were slighter and the worms which lived were fewer and less well grown than in five control dogs who all were primarily infected at the same time as the others were reinfected, the same amount of the same infective material being used in all cases.

It has been asserted that when a cured patient becomes reinfected his last state is deplorable. These findings suggest that it may be otherwise, particularly as Ozawa holds that injection of a vaccine prepared from schistosomes immunises as satisfactorily as a previous infection. The Bombay workers call urgently for the adequate serological and pathological investigation of human cases of infection by male schistosomes alone. Perhaps these cases hold the key to the acquisition of an acquired immunity. There is, at all events, need for early intensive study of a matter which affects the health of millions.

MEDICINE AND THE LAW.

The Death Sentence.

THE Select Committee on Capital Punishment has made three definite recommendations. These are, first, that a Bill be forthwith introduced and passed into law for abolishing the death penalty for an experimental period of five years in cases tried in civil courts in times of peace; secondly, that meanwhile the Royal prerogative of mercy should be exercised in all cases in England and Scotland to commute the death sentence; thirdly, that the substituted penalty be the penalty now attached to reprieved murderers. Alternatively, if Parliament should decide to retain the death penalty, then the Committee makes four other recommendations: (1) the rules in McNaghten's case to be "revised" so as to give fuller scope to general medical considerations, and to extend the area of criminal irresponsibility in the case of the mentally defective and of those who labour under some distinct form of insanity; (2) the death penalty to apply, in law, to women on the same terms as to men, and the Home Office and Scottish Office, when tendering advice as to the exercise of the prerogative of mercy, to continue to take each case on its merits; (3) no one under 21 to be sentenced to death; and (4) a larger exercise of the prerogative of mercy, the line to be raised higher and this change to be effected by resolution of the

[4] Japan. Jour. Exper. Med., 1930, viii., 79.

House of Commons. The next step lies with the Home Office, and the Home Secretary has announced that he means to take time to study the Committee's report, though doubtless he will be pressed to take immediate action in respect of outstanding sentences.

The report,[1] indeed, well deserves study. Garnished with not a little literary and theological citation, it gives an interesting historical summary of the gradual mitigation of the past severities of our law. It is a pity that, although the report presents the appearance of unanimity, it does not contain the views of several members of the Committee, who, it will be remembered, withdrew from the deliberations. No doubt the opinions of these absentees, who happened to include the majority of the representatives of the legal profession, will be expressed later in Parliamentary debate or otherwise. The general conclusion of the report is that the abolition of capital punishment will neither endanger life or property nor impair the security of the State; in support of this conclusion the experience of foreign countries is adduced. It is urged that successive mitigations of punishment in England have not had the ill-effect which opponents foretold. The main arguments on both sides are well enough known. The abolitionists uphold the sacredness of human life; they point to the fallibility of human justice, the doubtful value of capital punishment as a deterrent, the brutalising effect of executions, and the reluctance of juries to give a true verdict when the only punishment is death. The anti-abolitionists reply that capital punishment is the greatest deterrent to premeditated murder, that, if this deterrent is removed, burglars and other criminals will more readily carry and use lethal weapons, and that at present the death sentence is not inflicted where there is any legal or moral doubt. In this connexion the latest available statistics for England show that in 1928, when 23 males were condemned to death, 9 sentences were commuted "in mitigation of sentence"; these words are explained as meaning that weight is given to a recommendation from the judge or to such extenuating circumstances as youth, provocation, or mental disturbance. In the 50-year period from 1880 to 1929 there were 564 reprieves against 713 executions; in the 30-year period from 1900 onwards there were 327 reprieves against 423 executions; in the 10-year period from 1920 there were 91 reprieves against 138 executions. The first of the Committee's conditional recommendations—that the criminal irresponsibility of the insane be enlarged—will give an opportunity to review the Atkin Committee's report, issued in 1923 after the case of Ronald True had stirred public feeling, a report which never satisfied the medical profession. The second recommendation—for sex equality—may be logical but is probably contrary to popular sentiment. The third—as to the age-limit—may secure general support. The Children Act of 1908 forbade the hanging of young persons under 16. So far as this step gave statutory backing to existing practice, it was a modest effort for actually no one under 18 has been hanged for 40 years; a further raising of the age-limit both in practice and in statutory recognition thereof may now be due.

As to the substantive recommendations of the Select Committee there will be weighty critics who think a 5-year experimental period too short. Many would wish to see some move towards checking the exaggerated publicity given to crimes of murder. The views of the Home Office witnesses before the Select Committee are not clearly given in the report, but will presumably appear later in the Minutes of Evidence. It would be surprising if the Home Office did not deprecate undue reliance on the Royal prerogative of mercy, for there has been in the past the strongest reluctance to use that weapon as an instrument of policy. If public opinion favours the abolition of the death penalty, Parliament should give effect by statute to the general wish. The growth of restrictions on the occasions when capital punishment may be imposed for military offences may be seen in the Army and Air Force (Annual) Acts of 1925, 1928, and 1930. The recent report will help to focus public opinion on a problem which ought not to be approached merely along the lines of party politics.

Dangerous Drugs Act Records Inspection.

The Dangerous Drugs (Consolidation) Regulations, as every medical practitioner knows, require the keeping of various records of drugs or preparations supplied. Article 11 of the Regulations, dealing with the registers to be kept (including the "day book" and "separate book" maintained by a duly qualified medical practitioner), enacts that all these records are to be kept on the premises and are to be "at all times available for inspection." These last words, one has always supposed, are to be interpreted with reasonable latitude. Some light on their construction has been thrown by recent proceedings in what seems otherwise rather too trivial a case to have justified police intervention. The manager of a chemist's shop at Liverpool kept the requisite register. It was kept in a locked cupboard of which he himself carried the key. One day last February he went out to lunch about midday, taking the key with him. A few minutes later a chief inspector of police came to the premises to inspect the register which, being locked up, was not at the moment "available for inspection." The inspector went away, returned later in the afternoon, and then duly inspected the register which was then produced by the manager. In these circumstances the manager was charged with a breach of the regulations. His defence was the sensible reply that "at all times available for inspection" must mean "at all reasonable times," and that there was no evidence that the register was not available for inspection at all reasonable times. The Liverpool stipendiary magistrate nevertheless convicted the defendant and fined him 20*s.* and, on a case being stated to the High Court, the King's Bench Division has held that the conviction was right. The judges did indeed say that some limitation must be put upon the words "at all times," inasmuch as Parliament could not have intended that the register should be available in the middle of the night or on Sundays when the shop was shut. But they held that a reasonable limitation was to construe the words as meaning "at all times when the premises are open for business." The regulations did not require that the authorised person must be at all times available, but that the register must be at all times available; so, if the authorised person left the premises, he must either leave the key of the cupboard with an assistant or must not lock the register up. Another point had been taken by the defendant—namely, that the business belonged to a limited company, he himself being the manager under the direction of the superintendent appointed by the company for the purposes of Section 3 (4) of the Poisons and Pharmacy Act of 1908. He contended that, according to the regulations, the person who is responsible for keeping the register is the person who "keeps open shop for the purpose of retailing poisons"; this person, he said, was the company and not himself. The judges held, however, that the person bound to keep, and make entries in, the register is the person authorised to manufacture and sell drugs. This was the defendant; he had failed to have the register at all times available and was rightly convicted.

---

[1] H.M. Stationery Office. 1*s.* 6*d.*

If "at all times available for inspection" in the case of a chemist's register means at all times when the premises are open for business, what will the words be interpreted to mean in the case of the records of a medical practitioner? The doctor is on duty, if his services are required, at any moment, day or night. Is it to be suggested that his day book and separate book must be available for inspection at any minute of the 24 hours? The rather arbitrary action taken at Manchester suggests that Article 11 had better be re-drafted.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

GOVERNMENT GRANTS AND HOSPITAL SWEEPSTAKES.

FOR many years certain of the Dublin hospitals have been in receipt of Government grants. Most of them date from the eighteenth century, and were originally made by the old Irish Parliament, although in some cases the amount has been varied. They were made at various times in response to special appeals or to meet special conditions of the day. They vary greatly in amount, some being for small sums such as £50 or £100 a year, while in the case of the House of Industry Hospitals (Richmond, Whitworth, and Hardwicke) the annual grant, until quite lately, was £7000. This was almost enough for its upkeep, and before the war it made little appeal to public charity. It was, in fact, generally regarded as "a Government hospital," and the members of its staff and of its board of governors have to receive the approval of the Government before formal appointment. After the war this hospital found the Government grant insufficient for its needs, and it sought other sources of income, both in subscriptions from the charitable public and in contributions from patients. In recent years the Government grant has varied, and its amount in the present year was £5000. The House of Industry group of hospitals did not share in the recent sweepstakes on behalf of certain Dublin hospitals, but it has been accepted as a participant in the next sweepstake. The Meath Hospital, which also receives a Government grant, is in similar case. These hospitals have now been notified by the Department of Finance of the Irish Free State that, in view of the benefits they are likely to receive from sweepstakes, it is not intended to make provision for any grant to them in the estimates for the coming year. This is a severe blow to the hospitals, and one which they did not expect when they decided to share in the sweepstake. The attitude of the Department of Finance, however, is quite intelligible, if one may assume that the results of future sweepstakes are going to equal those of the past. It is to be noted that the threatened withdrawal of the Government grant only refers to the present year. Some question arises, indeed, as to whether the Government can withdraw its grants by a mere departmental minute. It is suggested that some at least of the grants to hospitals have a statutory basis and that they cannot be withdrawn except by fresh legislation. No doubt this is a matter which will be carefully considered by those responsible for the management of the finances of the several hospitals.

OPTICIANS AND "OPTICAL BENEFIT."

Some months ago it came to the knowledge of the Irish Medical Committee that the National Health Insurance Commissioners of the Irish Free State were giving their approval to a scheme of "optical benefit" for insured persons, under which glasses were to be supplied by opticians without any surgical examination of the eye. The Irish Medical Committee drew the attention of the Commissioners to the danger of permitting glasses to be ordered without a proper examination of the eye, as opticians had not the requisite surgical and pathological training to discover other than mere optical defects. The Committee suggested that glasses should only be supplied on the prescription of ophthalmic surgeons. The Commissioners have now replied, declining to accept the suggestion of the Committee on the ground that it would have the effect of precluding a large number of insured persons from participating in optical benefit because "(a) the number of ophthalmic surgeons is limited, and they are only available in the cities and larger towns of the Saorstat; and (b) the money available for optical benefit is limited, and the provision of optical appliances on the recommendation of qualified opticians affords the widest field for the benefit of the insured persons."

The use of the term "qualified opticians" by the National Health Insurance Commissioners cannot pass without protest. The word "qualified" suggests not merely a certain degree of skill, but a recognition of such skill by some competent authority, itself recognised by the State. For example, a "qualified medical practitioner" is a registered medical practitioner, and a qualified dentist is similarly a registered dentist. Neither in this nor in any other sense are there "qualified opticians" in the Irish Free State, for the possession of a diploma granted by some association or other, not itself recognised by the State, is no evidence of qualification. The use of the term by a Government department is peculiarly mischievous in that it is likely to suggest to the public that there is a class of opticians possessed of some legal or quasi-official status. Moreover, the suggestion of the Commissioners that it would not be practicable to arrange for the examination of claimants for benefit by an ophthalmic surgeon is not convincing. It is true that the number of such surgeons outside the larger towns is small, but the proportion of insured persons outside the larger towns is also small. It would be quite possible to arrange for an occasional visit by an ophthalmic surgeon to areas where none is ordinarily available, and the expense of such visits would not be prohibitive. Such visits have been arranged in some areas in connexion with the medical inspection of school-children, and many of the county hospitals have a visiting ophthalmic surgeon. The Commissioners do not appear to have given due consideration to the dangers which may arise from the overlooking or cloaking of serious disease by the provision of spectacles by persons without medical training.

TELEPHONES AND MEDICAL SERVICE IN RURAL AREAS.

Dr. Sean Tubridy, a dispensary medical officer in Connemara, has drawn the attention of the commissioner in charge of the public services of County Galway to the need for extension of the telephone service in remote districts. He points out that a messenger [illegible]t to sum[illegible]m may have to travel as much as 20 miles, thereby causing a delay which, in some cases, may lead to loss of life, and in all cases to great hardship. He asks that the country post offices should be equipped with telephone facilities. The commissioner promised to give the matter his immediate personal attention. The problem is, however, not peculiar to Connemara.

RETIREMENT OF COLONEL FORREST.

Great regret has been caused by the decision of Colonel J. V. Forrest to retire from the position of medical superintendent of the Royal Victoria Hospital, Belfast. Colonel Forrest has rendered invaluable services to the hospital during the past ten years. He took a very active part in supervising the large extensions to the building which were opened a few years ago, and he made important suggestions for their planning. His coöperation and wise counsel were especially helpful in connexion with the new maternity hospital and new children's hospital which are being erected in the grounds adjoining the Royal Victoria Hospital.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

A CHECK ON HEALTH INSURANCE CLAIMS.

THE presidential order mentioned in my letter last August (THE LANCET, 1930, ii., 419) has become law by the agreement of the Reichstag, and has had the desired effect of reducing the expenses of the Krankenkassen (sick-clubs). It may be recalled that the most striking provision of the order was that every insured person desiring to consult a medical man has to pay 6*d*. for a voucher allowing him to do so, and the same amount for every prescription in a pharmacy. This, of course, made possible considerable reductions in contributions to the Krankenkassen by their members, but another result has been that patients often abstain from consulting a medical man or do not fetch the prescribed medicine because they cannot or will not pay the sum demanded. This has applied not only to slight ailments for which a medical man would not have been consulted at all if he was to be paid by the patient himself, but also to severe cases such as injuries, infections, and venereal diseases. Another consequence has been that the number of patients in hospitals has diminished considerably because members of Krankenkassen, who form the great majority of hospital patients, are, except in urgent cases, admitted only on the order of medical men, and these, for the reasons stated, are consulted less than formerly. In the Berlin hospitals in ordinary times without an epidemic 6–8 per cent. of the existing beds are unoccupied, but this number has now risen to 16–20 per cent., and an old Berlin hospital, which for many years has served as a reserve hospital for light cases, has had to be closed in consequence. In Frankfort o/M the municipal health office reports that only 73 per cent. of their beds are occupied.

Under a new order just published the unemployed members of Krankenkassen are exempted from paying for the voucher, whilst other categories, notably persons suffering from infectious diseases, tuberculosis, and venereal diseases, will have to pay a smaller sum.

RELIEF OF PAIN IN CHILDBIRTH.

Prof. Hugo Sellheim, the well-known professor of gynæcology at Leipzig, writing in the *Centralblatt für Gynäkologie*, says that the pains of delivery must be alleviated notwithstanding religious contentions, and recommends the administration of narcotics. Small doses, he says, do not delay labour, but rather regulate it by strengthening bearing down. In order to help every woman in labour, including those without medical assistance, Sellheim has composed what he claims is an efficacious and innocuous preparation to be kept ready in pharmacies. He calls it Scopan, and it consists of half of the maximal doses of omnopon and of scopolamine. According to the instruction printed on the bottle for the midwife, the compound must be given about 30–40 minutes before the probable passing of the head through the pelvic outlet. As omnopon and scopolamine are among the remedies which may not be sold without a prescription, the medical man may prescribe the compound during pregnancy to be handed to the midwife. If severe pains develop in the first stage of labour half of the dose may be administered at this stage.

A HOME FOR DIABETIC PATIENTS.

In Garz, on the island of Rügen, on the Baltic Sea, a home for diabetic patients of the working classes has been opened. Such people have hitherto had to stay in a public hospital because the cure in a sanatorium is too expensive. When working they are not in a position to follow the dietetic prescriptions. The feature of the new home is that the patients, during their stay, may work and are paid for their work. Their expenses will thus be small, and they may stay a comparatively long time in the home, which has not the character of a hospital. Belonging to the home there are estates where the patients can do agricultural and gardening work, and workshops where they can pursue their own trade. The staff will partly consist of diabetic patients.

ALUMINIUM AND COOKING.

The use of cooking utensils made of aluminium has been held responsible for many diseases, especially for the increase of cancer. Prof. K. B. Lehmann, of Würzburg University, has lately examined the alleged dangers of aluminium vessels, and points out that the statement that cancer has increased tenfold in U.S.A. since the introduction of aluminium vessels is erroneous according to the official statistical records. Aluminium, he says, has no action on the heart or the vessels. Natural food contains an average daily quantity of 20–25 mg., and if aluminium vessels are used, about 40–60 mg. In America where the use of baking powder with aluminium is allowed, about 250 mg. are daily swallowed, but this quantity is too small to do any harm to the consumers.

AUSTRALASIA.

(FROM OUR OWN CORRESPONDENT.)

MEDICAL REGISTRATION IN THE FEDERAL CAPITAL TERRITORY.

ON Nov. 1st, 1930, an ordinance came into force which provides for the registration of persons engaged in medical practice in the Federal Capital Territory, which has an area of 940 square miles with an estimated population of a little over 9000. The administration will be in the hands of a board of medical practitioners which will, in the first instance, consist of Sir Colin Mackenzie, Dr. M. J. Holmes, Dr. L. W. Nott, and Dr. A. G. Butler. Appeals from the decisions of this board will be to the High Court of Australia. Most of the rules are in accordance with those of the various States of the Commonwealth, but the following clause is not included in any of the Acts in force in the States:—

> 34 (1) "A person other than a registered medical practitioner shall not (*a*) give or perform for fee or reward any medical or surgical service, attendance, operation, or advice; (*b*) advertise or hold himself out as being, or in any manner pretend to be, or take or use the name or title (alone or in conjunction with any other title, word or letter) of a physician, doctor of medicine, licentiate in medicine or surgery, master in surgery, bachelor of medicine or surgery, doctor, surgeon, medical qualified or registered practitioner, apothecary, accoucheur, or any other medical or surgical name or title; or (*c*) advertise or hold himself out, directly or indirectly by any name, word, letter, title or designation, whether expressed in words, or by letters, or partly in one and partly in the other (either alone or in conjunction with any other word or words, or by any other means whatsoever) as being entitled or qualified, able or willing to practise medicine or surgery, in any one or more or all of its branches, or to give or perform any medical or surgical service, attendance, operation or advice."

There are now seven different legal enactments in Australia governing the registration of medical practitioners, and a practitioner is compelled to seek fresh registration when he passes from one State to another.

ANTARCTIC RESEARCH.

The Mawson Antarctic Expedition is again leaving on Nov. 22nd from Hobart in the *Discovery*, this time to survey the antarctic region, from Cape Adare to Queen Mary Land, and the adjacent islands. Last year the expedition left from Cape Town and surveyed 1000 miles of coastline in the region of Enderby Land. Dr. W. Wilson Ingram, who is again accompanying the expedition as medical officer, has given a number of lectures in Sydney, describing the previous expedition and the prospects of the new one. Last year, he says, the health of the personnel was very good. There were a few minor casualties, but no serious illnesses. Owing to the difficulty of obtaining fresh meat, it was feared that scurvy might appear amongst the crew, and as only tinned food was available during the last three months of the cruise, a daily compulsory issue of fresh orange juice was made. This juice was obtained from the Tomango orange factory in Durban, carbon bisulphide and cane sugar being the preservatives used. This proved so successful on the last voyage that on this voyage 50 gallons of Australian orange juice preserved in the same way is being taken. The only sign of scurvy occurred in the steward detailed to issue the daily ration of orange juice, who apparently considered himself exempt from the ration. When visiting Kerguelen Island it was found that the famous Kerguelen cabbage, which was used as an antiscorbutic by Captain Cook, had been almost entirely eaten out by rabbits left by the German *Gauss* expedition. On the present expedition, for vitamin A a ton of Australian butter is being taken, and for vitamin B yeast cultures and yeast bread will be eaten instead of soda bread.

On the last cruise Dr. Ingram carried out a certain amount of bacteriological research, and examined the intestinal contents of some birds and fishes. He found that where parasites were absent from the intestines of birds, such as the Wilson petrel, the gut was sterile, otherwise not. He also found that culture plates exposed on the antarctic continent were sterile after five days incubation. Specimens of snow and ice examined were, in all cases, sterile. This is contrary to the findings of Dr. A. Maclean, the medical officer of the previous Mawson expedition, but agrees with those of Dr. Pirie who accompanied the Scottish national expedition. Before publishing any of this work Dr. Ingram intends to repeat these investigations aided by the knowledge gained on the previous expedition.

Dr. Ingram is an honorary physician to the Royal North Shore Hospital, Sydney, and since his return from the Antarctic, has been closely associated with the foundation at the Hospital of the Kolling Institute of Medical Research, of which he is Director. The building of this Institute is now almost complete.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

COST OF ILLNESS AND FUNERALS.

THE publications of the Committee on the Costs of Medical Care are now becoming more frequent. Publication No. 7 reports a study on capital investment in hospitals and is also published by the University of Chicago Press as a book "The Public's Investment in Hospitals." It is found that 7000 hospitals in the United States represent a capital investment of over 3 billion dollars. Most of this capital investment has been furnished by government and by non-profit associations. The hospitals are thus, generally speaking, owned by the public, and the public can only get a fair return if they are economically and fully used. The investment would be more profitable if hospitals were "integrated with the total medical activities—preventive, diagnostic, and therapeutic—of the community." Besides its regular publications the Committee is now issuing a series of "Miscellaneous Contributions."

The third of these is devoted to the expense of funerals, a subject that has been previously aired in this column. This study brings out very clearly the explanation of the excessive costs of burial in America. It is found that the proportion of undertakers to deaths has been steadily increasing since 1880. In that year there were 194·2 deaths per undertaker; in 1920 there were only 56·6. In New York City 8 per cent. of the undertakers handle 44 per cent. of the business. The remaining 92 per cent. of undertakers exist on an average of 25 funerals each per annum! In order to make a living out of two funerals a month it is obvious that the undertaker must fix his charges high. If the excessively high costs of funerals are to be reduced the business must be concentrated in fewer hands.

Another "Miscellaneous Contribution" (No. 5) inquires into the influence of illness and death in sending the public to moneylenders. It is found that no less than 28 per cent of the latter's customers come to him for emergency arising out of these causes. One bank reports: "in the last 20 months we have made available in cash to doctors, dentists, and hospitals more than $12,000,000 on behalf of [36,000] patients who otherwise might have had to forego proper care, might have had to ask charity, or else delay payment altogether." Interest on these loans is at a rate varying from 12 to 42 per cent. per annum. It is clear that the alternatives to health insurance are not without their drawbacks.

EFFECT OF THE ECONOMIC DEPRESSION.

Speaking recently over the radio, Dr. Thomas Parran, Jr., the Commissioner of Health of New York State, declared that there were already indications that a continued economic depression would be reflected in the death-rates, not only through retrenchment in public health expenditure, but also through the increase of such diseases as tuberculosis and infantile broncho-pneumonia that are favoured by poverty. In looking to the future Dr. Parran gave first place to research and second to the development of adequate administrative machinery in public health. "The pressing problem of the future," he said, "is to provide not only for preventive services through more efficient health departments but for treatment services through community hospitals and dispensaries in which the physician will be compensated for the services he renders; in which the patient will need to pay only for that part of the cost he is able to bear; and for which the community, through taxes, will bear the remainder of the cost of such services."

PUBLIC HEALTH SERVICES

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1929 statistics of three counties:—

Name of county and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Warwickshire (357,140)	16·3	12·7	0·87	1·30	2·5	2·2	60	34	4·3
East Sussex . (270,700)	12·7	13·7	0·73	1·85	2·4	2·9	50	21	2·9
East Suffolk . (209,950)	15·6	12·9	0·82	1·55	2·4	2·4	48	24	5·1

Registered stillbirths per 100 live births: Warwickshire —, East Sussex 3·4, East Suffolk 4·6.

Warwickshire.

Dr. A. Hamilton Wood reports that the death-rate is 2·6 up on that of the previous year, and that about 80 schools were closed as the result of the influenza epidemic. Two important applications have been made to the county council under the Local Government Act, 1929—one for a new water-supply in the rural district of Brailes, and the other for a sewage disposal scheme in that of Warwick. Progress is being made in preventing the pollution of the rivers. As the result of good work in the Upper Tame basin, and the improved modern treatment of Birmingham sewage Dr. Wood foresees the time when the Tame will no longer be dubbed the open sewer of Birmingham. As regards the Avon—the Leamington effluent is now satisfactory and the Warwick scheme is making progress, but the Coventry effluent is not likely to be much improved by the new works in progress for some two years. The Sowe, a tributary of the Avon, needs careful watching owing to innumerable small sewage works attached to building estates on the outskirts of Coventry. In June a conference of the interested authorities considered the formation of a Rivers' Board for the Severn, and expressed general approval of the proposal. Dr. Wood thinks it would still be desirable for county councils to retain their supervisory powers over the rivers in their areas, although actual inspection would be carried out by the technical officers of the Board.

During the summer there was a very long waiting-list of patients for sanatorium treatment, and a partially successful endeavour was made to provide for some patients in outside sanatoriums. Of the 5821 births, 3174 were attended by midwives as midwives. and 1032 by midwives acting as maternity nurses. The remaining 1615 were attended by doctors either alone or with the help of nurses or other persons unqualified to practise midwifery. There is surely little excuse now, says Dr. Wood, for the engagement during confinement of nurses or other persons who are not trained or certified as midwives. No new nursing associations have been formed, but considerable reorganisation has been done. Eight associations have now provided their nurses with cars and four with motor-cycles. Such antenatal work as is done is conducted by the county assistant medical officers. There were 283 new cases, 193 of which attended the clinics of the two county maternity homes. The Rugby home had an unfortunate outbreak of puerperal fever at the end of February, which was at first mistaken for influenza. Three patients were removed to hospital, where one subsequently died. Orthopædic facilities are mainly based on the hospitals at Coleshill and Manfield with other hospitals for "short stay" cases, and ten out-clinics. A new clinic was opened for the northern district in August, and when a proposed clinic at Solihull materialises the whole county will be covered. Owing to the expense, however, hospital provision has been limited and there were 32 cases on the waiting-list at the end of the year. The patients receiving treatment during the year numbered 749, 543 of school age, and 206 of pre-school age.

The only reference to the Housing (Rural Workers) Act, 1926) is the regret expressed by Dr. L. L. Fyfe (Stratford-on-Avon R.D.) that nobody has taken advantage of this Act.

East Sussex.

Dr. R. Ashleigh Glegg reports that during the year a scheme for the prevention and treatment of crippling was inaugurated. The scheme is based on Chailey Heritage Hospital, with out-patient clinics at Lewes, Hailsham, and East Grinstead. Dr. Murray Levick, hon. medical officer of the hospital, and the R.M.O. conduct the clinics and an orthopædic nurse attends them twice weekly to give treatment. The dental staff has been increased in order to deal with mothers and pre-school children. The three dental surgeons engaged in the work report that an encouraging start has been made. Dr. Glegg complains that only one of the local authorities in the county (Hove) takes samples of milk for examination as to tubercle infection, and he emphasises his complaint by pointing out that during the last four years 1651 cows have been slaughtered under the Tuberculosis Order, of which only 44 were discovered as the result of the sampling of milk supplied by farms in the county. If more adequate sampling were undertaken it would be possible to stop the milk of tuberculous cattle much earlier than at present. Dr. Glegg regrets the small use made of the Housing (R. W.) Act. Up to the end of 1929 grants for assistance in 14 cases had been made, totalling £1891.

East Suffolk.

Dr. B. Wood-White reports that the water-supply of the villages is in the main liable to pollution or inconvenient. Water from shallow ponds or wells is used for drinking purposes and much labour is spent in carrying water from distant wells. He anticipates that contributions from the county council under the L. G. Act, 1929, to wisely conceived rural water schemes will be money well spent. The town of Saxmundham has installed a sewerage scheme, and Woodbridge and Halesworth are now the only towns, with populations exceeding 1500, that have made no provision for a water-carriage system. For four years the Gipping was grossly polluted by silkworks at Stowmarket. At long last the works found a complete remedy and six months later were closed down for economic reasons. East Stow R.D. has made great progress in the erection of houses, the local authority having erected 166 during the year. Dr. Wood-White was called upon by the parish council of Tuddenham (four miles from Ipswich) to inspect the housing accommodation. The 67 houses in the parish, which he inspected, were much in need of repairs and at least 17 urgently required improvement, which could have been provided under the Housing (R. W.) Act. He regrets the small use made of this Act and considers 93 a sorry figure for the number of dwellings improved in his county in three years. Systematic housing inspection by the officials of the rural district council, followed by vigorous action, would soon make an enormous difference. Dr. Wood-White also points out that the tuberculosis order is of little or no avail without veterinary inspection of the herds. The 215 cases of diphtheria had the high case-fatality of 10 per cent. It is difficult to secure the attendance of adult contacts at the dispensaries, and there is no hospital accommodation for advanced tuberculosis among women in the northern part of the county.

PORT SANITARY AUTHORITIES.

London.

In his annual report to the Port of London Sanitary Committee for 1929 Dr. C. F. White mentions that the tonnage entering the port increased in the year by over a million tons. There arrived from abroad 15,932 vessels, but no cases of plague or cholera appeared, nor were any rats found infected with plague either on ships or on shore. Of small-pox four cases were sent to hospital and also 10 cases of typhoid fever from a ship that arrived from South Africa. The relation between the cases could not be traced. The chief infectious diseases mentioned as occurring were influenza, pulmonary consumption, chicken-pox, measles, malaria, and enteric fever; these among crews and passengers. The hospital at Denton, near Gravesend, got a new cleansing and disinfecting station, a new post-mortem room and mortuary. The boys' training ships were remarkably free this year from infectious diseases; Schick-testing and immunisation continued on the *Cornwall*. No diphtheria case is reported from any training ship. Venereal disease leaflets, notifying where free treatment may be obtained, are distributed to incoming ships. The sanitary inspectors made 15,616 examinations of vessels, 5450 of shore premises; the nuisance most frequently found was, in each group, want of cleanliness; on vessels 1417, ashore 914. Crew accommodation is being carefully considered, a new minimum standard is overdue, but that existing in many ships is far above the minimum. Defects are noted as regards leaks, lighting, heating, ventilation, and w.c.'s. Six rat-searchers were appointed, to work under the sanitary inspectors, to seek for evidence of rat presence and give special attention to ships from infected ports, visiting these last daily. They also examine the shore premises continuously and systematically, sending daily rats found dead or trapped—packed in linen bags wet with kerosine (which kills the fleas) and secured in tin boxes—to the pathological laboratory of the Dreadnought Hospital at Greenwich. Of 1275 examined this year none was found infected. This is all planned so that any plague infection of shore rats, if such should occur, shall be quickly discovered and treated. To kill rats on board, ships are fumigated with hydrogen cyanide or sulphur dioxide. Dr. White thinks that one company which fumigates its ships with hydrogen cyanide after every voyage, to get rid of insects, has made its ships "almost if not absolutely" rat-free. Persistent attention is given to rat-proofing of warehouses on shore. Two ships were convicted of causing nuisance by smoke. All the sanitary inspectors are also qualified as inspectors of food. Much assistance is given to them by custom house officers and by importers; inspection has been further lightened by the fact that this year it has been done more carefully abroad, particularly noticeable in relation to caseous lymphadenitis and actinomycosis. Of 22 thousand carcasses, 2 per cent. were condemned, but of those from New Zealand only 0·9 per cent. The food condemned and destroyed or otherwise disposed of amounted to no more than 1743 tons. Of 40,073 aliens, 23 transmigrants and 9 others were certified and refused admission. The canal boats inspected were 82; of these a quarter had children (averaging 4·8 in each) on board. Many new water-closets were provided in the docks. The water-supply of ships in the port is mostly direct from the mains; there are 20 water barges, all registered annually by the Port of London Authority, after inspection and approval by the medical officer.

Newport (Mon.).

Dr. J. Howard-Jones states that 5400 ships entered the port, and that 1507 were inspected—half of those from abroad, a fifth of those in the coasting trade; 358 of them showed defects, all of which were remedied. No case of plague or small-pox occurred; tubercle cases were fewer than the average. Of rats 1966—all black—were killed on board ships; 574—all brown—in the docks; roughly a quarter were males. No plague-infected rats were found. Drinking water is supplied to ships from the town mains; there are no water boats. The defects on ships were either constructional or sanitary. The constructional were chiefly poor lighting, too little table and seating accommodation in forecastles, insufficient food storage in "weekly" ships where each man provides his own rations, dampness by condensation or leakage. The sanitary defects on 358 ships included 217 dirty forecastles, 84 choked and foul w.c.'s, 42 ships had accumulations of refuse on deck, 37 had defective stoves, 19 are reported to have had verminous living spaces. Dirty or verminous beds to the number of 1938 were destroyed.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 20TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 138 (last week 137); scarlet fever, 2000; diphtheria, 1451; enteric fever, 22; pneumonia, 1152 (last week 997); puerperal fever, 38; puerperal pyrexia, 108; cerebro-spinal fever, 10; acute poliomyelitis, 6; acute polio-encephalitis, 1; encephalitis lethargica, 12; continued fever, 1; dysentery, 7; ophthalmia neonatorum, 107. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Dec. 23rd–24th was as follows: Small-pox, 167 under treatment, 4 under observation (last week 189 and 5 respectively); scarlet fever, 1790; diphtheria, 2026; enteric fever, 11; measles, 89; whooping-cough, 121; puerperal fever, 22 (plus 9 babies); encephalitis lethargica, 121; poliomyelitis, 2; "other diseases," 47. At St. Margaret's Hospital there were 11 babies with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 71 (1) from measles, 8 (0) from scarlet fever, 10 (0) from whooping-cough, 43 (7) from diphtheria, 62 (9) from diarrhœa and enteritis under two years, and 58 (11) from influenza. The figures in parentheses are those for London itself.

No death from small-pox was returned from areas outside the great towns for the month of November last. The fatal case of enteric fever mentioned above was reported from Birmingham. Twenty-one deaths from measles occurred at Liverpool, 18 at Hull, 6 each at Bristol and Swansea, 3 each at Ipswich, Walsall, and Grimsby. Eleven deaths from diphtheria were reported from Liverpool, 2 each from East Ham, Birkenhead, Salford, and Leeds. Diarrhœa accounted for 10 deaths at Liverpool, 4 each at Birmingham and Manchester. The number of stillbirths notified during the week was 207 (corresponding to a rate of 41 per 1000 births), including 39 in London.

CORRESPONDENCE

NEPHROSIS AND ŒDEMA.

To the Editor of THE LANCET.

SIR,—We have read with interest Dr. Epstein's comments on the paper by us which appeared in THE LANCET of Nov. 8th, 1930. We feel that this and previous publications by us indicate our appreciation of his pioneer work on the causation of œdema. Discussing the various points raised in his letter, we have been careful not to attribute to him the theory that a lowering of the blood plasma protein content will cause renal lesions, and we must insist that there is no confusion whatsoever in our statements on this subject. Our observations were such as to make a contrast between them and those of Barker and Kirk inevitable.

Turning to the next point in his letter, we entirely disagree with his statement that the type of plasmapheresis observed by us "is totally different from that resulting from excretion of protein by the kidneys." The causation of the ascites has nothing to do with the point at issue, and since the major blood changes *and the subsequent œdema are exactly similar to* those occurring in nephrosis we feel that our analogy is justified. We know of no published evidence in support of the statement that "the proteinuria of chronic nephrosis is of a different nature and is (Dr. Epstein believes) an instance of selective and preferential excretion." In so far as we are aware there is no convincing published evidence concerning alterations in the constitution of the protein molecule in the various body fluids such as plasma, ascites, &c., in various pathological conditions. In fact the publications of Hewitt indicate that the proteins of the urine and the blood are identical in these cases.

Because "histopathology has thus far failed to account for the proteinuria of chronic nephrosis" is no adequate reason for postulating a hitherto unproven alteration in the constitution of the plasma protein molecule. Dr. Epstein has focused attention on what appears to be a separate entity amongst the cases loosely defined as "Bright's disease." We shall be deeply interested if he is ultimately able to establish that the pathogenesis of nephrosis is entirely independent of the kidney.

We are, Sir, yours faithfully,
T. IZOD BENNETT.
E. C. DODDS.

VALUE OF RAMISECTION IN CASES OF SPASTIC WEAKNESS.

To the Editor of THE LANCET.

SIR,—Lord Moynihan complains that I have curtailed the passage from his Toronto address in which he spoke of "the somnolence of physiologists." He now gives the paragraph in full, and he emphasises the fact that he "quite deliberately made no reference whatever" to the value of ramisection in cases of spastic weakness. The significance of this omission did not escape me. But I may be pardoned for assuming that he referred to the work of Hunter and Royle on "The Influence of the Sympathetic Nervous System in the Genesis of the Rigidity of Striated Muscle in Spastic Paralysis"—for that is the only physiological research that these observers are known to have undertaken.

Perhaps Lord Moynihan will now tell us precisely to what other physiological researches he referred, when he wrote, "so the physiologists have similarly had their somnolence proclaimed by the researches of Royle and Hunter, Wade of Sydney, Robertson of Toronto, Judd, Adson, Learmonth, and others, as to the sympathetic nervous system, and its influence upon maladies so diverse as Raynaud's disease, Hirschsprung's disease, endarteritis obliterans, and retinitis pigmentosa." I gather that certain abdominal surgeons and others have recently discovered: (1) that the walls of the hollow viscera and the blood-vessels are largely composed of muscle; (2) that this muscle is supplied by the sympathetic nervous system; and (3) that division of the corresponding sympathetic nerve fibres produces an obvious physiological effect upon this muscle. These things and many more have been known to physiologists for many years. But surgeons generally have only just discovered that they are of some clinical importance.

It was obvious that, given a technique, which Hunter and Royle devised, for dividing the sympathetic *rami communicantes*, there were many diverse conditions which might be benefited by sympathetic ramisection. The surgeons named by Lord Moynihan, as well as others, have quite naturally explored these possibilities. But that is not physiological research. If "the carefully ordered sequence of names and the special list of diseases enumerated" by Lord Moynihan signify anything more than the clinical application of years' old physiological knowledge, we should very much like to know it. Meanwhile we retain our profound admiration for the work which physiologists have accomplished (in their sleep ?).

I am, Sir, yours faithfully,
A. S. BLUNDELL BANKART.

Harley-street, W., December 20th, 1930.

APPENDICITIS IN THE SCHOOLBOY.

To the Editor of THE LANCET.

SIR,—I read with interest Mr. Barrington-Ward's paper on this subject in your issue of Nov. 22nd, 1930. With most of his statements both the school doctor and the pædiatrist are likely to agree, but possibly the general practitioner, who sees appendicitis in earlier stages, may dissent from the view that 90 per cent. of the cases are obstructive. We know so little about the ætiology and onset of appendicitis that it hardly becomes us to talk dogmatically about what takes place in a first attack. I know that in my own case, as a boy and as an adolescent, varieties of diagnosis were made by very competent doctors, including some of the best-known surgeons and physicians on London hospital staffs. Since then I have been exceedingly sceptical of many of the "alternative diagnoses." However possible these may be in older children, in the case of schoolboys they rarely prove to be justifiable excuses for delaying operation. I know that scarlet fever, pneumonia, and, indeed, any acute or subacute infectious disease is still sometimes mistaken for an attack of appendicitis, just as frequently perhaps as in smaller children attacks of appendicitis are diagnosed "cyclic vomiting," "acidosis," or "glycopenic disturbance"; but surely no experienced practitioner will make that mistake. Mr. Barrington-Ward's surprise at the relatively small amount of physical discomfort which seems to attend such attacks in growing boys I cannot share, for one knows that at such ages peritoneal pain is much less acute than in young children or in adults. That, indeed, is the great danger of the disease in the puberal and post-puberal stage—its insidiousness and its rapid development into complications. I do not believe that it is more fulminant at that age, but the reason why one sees more fulminating cases then is because the signs do not give rise to symptoms. The reason for that again is not, probably, psychological, but merely physiological.

I regret that Mr. Barrington-Ward has not emphasised the importance of rectal examination in *all* cases of suspected appendicitis. It is one of the few ways in which one can differentiate a vesiculitis, a condition by no means uncommon in boys. Persistent vomiting largely depends on the condition of the boy's stomach at the time when he feels the colicky pain; as the patients are usually "off their feed" for at least 24 hours before they feel any other symptoms, vomiting is much rarer than it is in small children or in grown-ups. I have found unilateral dilatation of the pupil and unilateral flushing of the face on deep pressure on the affected side of distinct use in the differential diagnosis.

May I add one word in regard to operation? As a pædiatrist I much object to the statement "no preliminary treatment is necessary." The prolonged convalescence in these cases, the sometimes serious psychological after-effects of the operation itself, and the discomfort of the patient can all be avoided, in my opinion, by proper and adequate feeding before the operation. There can be no possible objection to allowing the boy to be operated on to suck barley sugar, drink sugar and water solutions, or partake freely of weak sweetened tea before the operation, nor to allowing him carbohydrate solutions immediately he gets conscious after the operation. With proper feeding morphia is entirely unnecessary in uncomplicated cases, convalescence is much shortened, and the comfort of the child much enhanced. I still fail to see why my surgical colleagues are so impressed by the antiquated custom that nothing should be given by mouth after such operations except water, and my own view is that rectal salines and glucose are much more likely to lead to peristalsis, discomfort, and, in suppurative cases, to atony, than free administration of watery solutions by mouth.—I am, Sir, yours faithfully,

C. LOUIS LEIPOLDT,
Visiting Pædiatric Physician, New Somerset Hospital, Cape Town.
Dec. 9th, 1930.

BACTERIOLOGICAL EXAMINATION OF WATER.

To the Editor of THE LANCET.

SIR,—Your series of special articles on Clinical Interpretation of Aids to Diagnosis has been much appreciated by a legion of readers. I have been specially interested in Nos. LXXXVIII. and LXXXIX., as the subject Bacteriological Examination of Water is one to which I have devoted a lifetime of study. I am so closely in agreement with most of what Prof. Beattie has written that I trust he will forgive me for offering a few words of *constructive* criticism.

I think Prof. Beattie has rather missed the point that the basis of British water bacteriology was founded, over a quarter of a century ago, on the bacteriological correlation, quantitatively and qualitatively, of impure substances—e.g., fæces and sewage—with waters of diverse sort including those remote from undesirable pollution. The colon bacillus, the streptococcus, and, but to a less extent, the *B. enteritidis sporogenes* (now more commonly called *B. welchii*) tests are examples of tests which form the keystone of the arch which has placed this country in the van of progress in water bacteriology. We greatly fear the contamination of water with excremental matters, but logically we should not condemn or appraise water, or frame standards, without exploiting our precise knowledge of the quantitative and qualitative bacteriology of these objectionable substances and of the relative (or absolute) absence of comparable bacteria from waters which have escaped the scourge of civilisation—fæcal pollution.

I do not venture to criticise Prof. Beattie's standards, although some may think that they err a little on the side of generosity—a seasonable virtue at the close of 1930. He makes no allusion to Wilson's bismuth sulphite iron medium in connexion with search for typhoid bacilli. Doubtless he has not wished to overburden his narrative with highly technical matters, but there are several things to be considered in connexion with water-supply—e.g., sources and final product. In relation to the former, Wilson's medium has thrown, in my opinion, a fresh flood of light on water bacteriology.

I am, Sir, yours faithfully,
ALEXANDER C. HOUSTON, M.B., D.Sc.
Fairhazel-gardens, N.W., Dec. 29th, 1930.

A PLEA FOR MORE CAREFUL TONSILLECTOMY.

To the Editor of THE LANCET.

SIR,—I am surprised that there has been no reply to Mr. McLaggan's plea for more careful tonsillectomy which appeared in your issue of Nov. 22nd, 1930 (p. 1150). As a general practitioner, it is with much diffidence that I add my plea to his. I have had ten years' experience as a clinical assistant to an ear, nose and throat department, and differ perhaps from a specialist in that any private patient on whom I operate usually attends me afterwards and the end-results are known to me. In consequence I cannot risk doing any work that would allow of criticism to be made at a later date. The old inexactitude that the tonsils have grown again must become a defence of the past, and it is preferable to tell a patient, if tonsillectomy has been incomplete, that part has been left behind and may at a later date have to be removed.

There is a growing tendency to attack medical men on very little provocation, and it is not improbable that a case may yet be fought on the failure of a surgeon to complete the operation of tonsillectomy for which he receives his fee. In private, I invariably dissect out tonsils under full anæsthesia, and in children this operation can be completed in under ten minutes, with less bleeding, less shock, and none of the dramatic risks such as take place under the short anæsthetic that is required for guillotining. It is perhaps because the guillotine appears to be so simple an instrument, when in fact it is most difficult, that its use is taught in the medical schools. I do not think I am exaggerating if I say that it is necessary to do at least 100 operations with the guillotine before becoming an adept with it, and even the adept cannot invariably remove the lingual portions of the tonsils. These experimental cases may become rheumatic or deaf, and are no credit to the profession. On the other hand, with the full exposure and excellent illumination that can be obtained with a Boyle-Davis gag and head light, a house surgeon can be taught efficiently to dissect out the non-adherent tonsils of children in a very short time, whilst at the same time any faults he makes can be rectified before the child is away from the table.

As a clinical assistant, seeing and treating the old cases, one realises only too well how much damage one may have caused to a child's hearing by an incomplete tonsillectomy, especially if it was done primarily to cure an otitis media. It is to be hoped eventually some form of treatment may be discovered which will do away with the mutilating operation of tonsillectomy, but in the meantime I wish most emphatically to support Mr. McLaggan's plea.

I am, Sir, yours faithfully,
C. BERKELEY WAY, M.B., B.S. Lond.

Finchley-road, N.W., Dec. 29th, 1930.

THE TOXICITY OF VITAMIN D.

To the Editor of THE LANCET.

SIR,—Last year a boy 2 years old crippled with rickets was brought to my clinic. I prescribed *vigantol in three-drop doses to be taken in a teaspoonful* of hot milk thrice daily. The mother misunderstood both my and the pharmacist's directions and she administered to her baby a teaspoonful of vigantol three times on the day she consulted me. On the morrow the little patient was again in my clinic. He was œdematous from head to foot, and his urine contained a considerable amount of albumin. No other abnormality could be detected. Vigantol was stopped; a purge was administered; hydric diet, absolute rest, and warmth completed the therapeutic measures taken. On the third day the child was quite himself again and resumed the daily dose of nine drops for a period of *two months uninterruptedly* before he could get rid of his rickets.

I contribute this case to show how wide is the range of dosage in vitamin D therapy.

I am, Sir, yours faithfully,
DR. DJAMIL F. TU-TUNJI.

Trans-Jordania, Nov. 14th, 1930.

PASTEURISATION OF MILK.

To the Editor of THE LANCET.

SIR,—In any process or system designed to render milk safe for human consumption, it is essential that possible undesirable effects on the biochemical and nutritive properties should be accurately ascertained and considered. In the letter of Lord Dawson and his co-signatories, it is definitely stated that during pasteurisation the vitamin content remains intact. There is, however, an impressive weight of evidence that points to the conclusion that there is a notable loss of vitamin C and that the calcium salts are considerably affected. The bibliography on these points is so extensive and well known that specific references are unnecessary.

I am, Sir, yours faithfully,
JOHN CAMPBELL, Ph.D.

East Dulwich, S.E., Dec. 22nd, 1930.

PANEL AND CONTRACT PRACTICE

National Health Insurance in 1930.

THE past year was clouded by rumours of excessive sickness benefit claims, culminating in the report of the Government Actuary on the experience of a group of approved societies during the period 1921–27. The increase was shown in the report to be: (1) most pronounced in the claims of short duration; (2) due more to the larger proportion of persons claiming than to a longer average duration of claims; (3) more marked among women than men, and among married than unmarried women. These facts suggested directions in which remedies are to be sought. Two investigations were made by the Ministry of Health, the first being a scrutiny of the references to the regional staff in the year 1929, the other an investigation of a sample of insured persons in receipt of benefit at a given date in 1930. The results of the first were tabulated in Sir George Newman's annual report. The results of the second are in process of compilation. Certain of the larger approved societies were requested to refer for examination a fixed proportion of all their members who on a certain day (May 5th, 1930) were in receipt of sickness or disablement benefit. About 29,000 such references were received and reports from the practitioners in attendance were obtained. These were scrutinised and those clearly incapable were excluded. The remainder, about 13,500 in number, were summoned for clinical examination and report by the regional staff. New regulations are now in force whereby certificates are to be investigated and practitioners referred to panel committees to decide on the evidence of "want of reasonable care."

The National Formulary, or list of commonly used prescriptions similar to a local hospital pharmacopœia, issued at the end of 1929, has been adopted in most areas during 1930. It is generally regarded as useful and marking an advance on the local formularies which were formerly in use.

During the year additional benefits have not shown much development owing to want of adequate funds. *The most popular are the dental and ophthalmic* benefits, and to these have been allotted the most money. The waiting period which must elapse before an insured person becomes entitled to additional benefits, which prior to January, 1930, was about five years, has now been shortened to three. Unfortunately, these additional benefits, which are of great service to insured persons from the preventive point of view, are crippled by the depleted state of the sickness benefit funds.

The best hope for the new insurance year lies in a resuscitation of trade and increase of employment, resulting in such improvement in economic conditions as to lighten the present burdens. Energies might then be turned into more productive channels for the prevention of sickness and preservation of health.

Statutory Rules and Orders No. 781.

Towards the end of last year certain regulations came into force embodying agreements between the Ministry of Health and representatives of insurance practitioners. One of these gives effect to the arrangements whereby facts which appeared prima facie to indicate that insurance practitioners had issued certificates without the exercise of reasonable care might be brought to the notice of practitioners by regional medical officers; certain of these cases are then brought to the notice of panel committees, for that committee to satisfy itself that there had been lack of proper care before any disciplinary action on the part of the Minister. Hitherto, any question raised by an approved society as to the action of a practitioner with regard to any medical certificate which he is required to furnish to a member of that society has been referred to the medical service sub-committee (a committee of doctors and laymen) for investigation. Power is now given to the Minister to refer the question of the certificates given by a practitioner to a panel committee (a committee of doctors only) or a similar committee representing a larger area. Any reference to a panel committee must be accompanied by a written statement indicating the points on which an explanation is required. The panel committee has to furnish the practitioner with a copy of the statement and arrange for him to submit a reply and to appear before them; representatives of the Minister attend the hearing. The panel committee's report and recommendation are forwarded to the Minister, the practitioner being provided with a copy. Both the practitioner and the Minister have the right of appeal.

Another regulation provides a means of deciding whether the substance or article supplied by a chemist or an insurance practitioner to an insured person was a drug or an appliance forming part of medical benefit. The decision is left to the panel committee after considering any representations made to it by the pharmaceutical committee; if the practitioner appears before the committee, a similar opportunity must be given to a representative of the pharmaceutical committee and of the Minister. Where the substance or article ordered by the practitioner has been found not to be part of medical benefit, the amount of money representing the cost of the article is calculated in a prescribed manner, deducted from his remuneration, and any moneys so recovered paid into the chemists' fund or the practitioners' drugs account as the case may be.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lts. C. T. Hyatt to *Courageous*, and T. L. Cleave to *Penzance*.

TERRITORIAL ARMY.

M. E. D. Roberts (late Cadet Corpl., Marlborough Coll. Contgt., Jun. Div., O.T.C.) to be Lt.

Supernumerary for service with O.T.C.—S. Andrews (late Cadet Staff-Serjt., Queen's Univ. Belfast Contgt., Sen. Div., O.T.C.) to be Lt.

ROYAL AIR FORCE.

M. Pearson is granted a temporary commission as a Flight Lt.

Flight Lt. B. F. Haythornthwaite is promoted to the rank of Squadron Leader.

Flight Lt. V. V. Brown is transferred to the Reserve, Class D (ii).

Dental Branch.—Major L. Somerville-Woodiwis (Army Dental Corps) is granted a permanent commission as a Squadron Leader.

INDIAN MEDICAL SERVICE.

The undermentioned officers relinquish their temp. commns.: Capts. J. Sahai and R. U. Hingorani.

Appointments

FORSYTH, C. E. P., M.B., Ch.B. Aberd., D.P.H., has been appointed Hon. Asst. Physician, Royal Gwent Hospital, Newport, Mon.

HUNT, ELIZABETH, M.D. Liverp., Physician to the Skin Department, South London Hospital for Women.

Queen Charlotte's Maternity Hospital: NIXON, W. C. W., F.R.C.S. Eng., Senior Resident Medical Officer, STANSFIELD, F. R., M.B., B.S. Lond., F.R.C.S. Eng., Assistant Resident Medical Officer, STUART, M. S., M.R.C.S., L.R.C.P. Lond., and LENDRUM, C. E. L., M.R.C.S., L.R.C.P. Lond., Resident Anæsthetists.

Royal Northern Hospital: LOVE, R. J. McN., M.S. Lond., F.R.C.S. Eng., and BAILEY, H., F.R.C.S. Eng., Surgeons.

MEDICAL NEWS

University of Cambridge.

At recent examinations the following candidates were successful:—

THIRD EXAMINATION FOR M.B. AND B.CHIR.

Part I.: Surgery, Midwifery, and Gynæcology.—G. L. Alcock, P. T. Ashby, C. P. Bailey, J. S. Barker, W. D. Bell, F. K. Boston, L. V. O. Brown, W. D. Brown, H. S. Buckland, D. C. Carroll, C. L. Collins, J. G. Connell, E. J. Currant, A. Cursham, J. H. Cyriax, E. M. Dimock, D. Divine, A. Eckford, W. A. Fell, F. H. Finlaison, G. H. Gange, G. H. A. Graetz, G. N. Grose, C. A. Grove, G. D. Kersley, C. R. T. Lane, T. C. Larkworthy, D. L. Lewis, J. W. S. H. Lindahl, E. H. W. Lyle, D. G. Macdonald, D. B. McGavin, F. H. Morrell, W. M. Niblock, W. R. Parkes, M. G. L. Perkins, J. Petro, W. H. Poole, J. Richardson, M. A. Robertson, M. A. Rushton, W. W. Sargant, P. G. Scott, R. P. W. Shackleton, J. Sowerbutts, J. H. Spence, T. C. Stamp, J. W. Summerhayes, C. E. Taylor, A. R. Thomas, R. M. W. Turner, E. D. Ward, J. N. Warren, A. M. Weston, J. C. G. Whitelaw, F. J. Wright, and C. H. Wrigley.

Part II.: Physic, Pathology, and Pharmacology.—C. Arthur, H. B. Bagshaw, C. O. Barnes, J. H. Beilby, J. H. Conyers, R. M. S. Cross, E. M. Dimock, D. Divine, W. S. Dyson, A. B. Field, F. H. Finlaison, M. S. M. Fordham, E. D. Forster, G. E. Grove, J. H. Hall, C. J. K. Hamilton, J. O. Harrison, W. V. Howells, G. H. Jennings, J. J. Keevil, H. D. B. Kelly, W. A. Nicholson, G. L. Ormerod, P. H. L. Playfair, V. H. Riddell, N. H. L. Ridley, M. E. D. Roberts, M. A. Robertson, G. Roeyn-Jones, E. M. P. Smith, R. H. B. Snow, D. J. R. Steen, E. S. Stern, H. Taylor, B. C. Thompson, J. W. P. Thompson, W. R. Winterton, and F. J. Wright.

The election to the Downing professorship of medicine has been suspended until March 31st.

University of London.

At recent examinations the following candidates were successful:—

M.D.

Branch I: Medicine.—A. J. Amor, G. C. Babington, L. I. M Castleden, W. P. M. Davidson, C. P. Donnison, Margaret R Dunlop, Doris L. Durie, Horace Evans, *H. P. Himsworth A. B. Kettle, G. O. Mitchell, M. B. Mody, M. M. Posel, L. H. Savin, A. G. Watkins, Dorothy E. Wright, and Elsie B. Wright.

Branch IV: Midwifery and Diseases of Women.—Mary C. E Constantine, Victoria M. Crosse, Helen R. Goodman, Beatrice G Smith, Edith J. L. Smith, Jean S. Thomson.

Branch V: State Medicine.— Amelia M. Ison and E. H. R Smithard.

M.S.

Branch I: Surgery.—D. S. M. Barlow, *R. H. Boggon, M. A Paul, R. F. Phillips, and S. M. Power.

Branch IV.: Laryngology, Otology, and Rhinology.—*R. J Cann and W. A. Mill.

* University medal.

Ten lectures on Comparative Physiology will be give by Mr. G. P. Wells at University College, Gower-street W.C., at 5 P.M. on Fridays from Jan. 16th to March 20th Admission without ticket.

University of Sheffield.

At recent examinations the following candidates we successful:—

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—Margaret F. Coveney, A. W. R. Eardley, J. E. Edso and T. A. Hunt.

Part II.—C. England and A. Spencer.

Queen's University of Belfast.

On Dec. 20th the following degrees were conferred:—

M.D.—George Smyth.

M.B., B.Ch., B.A.O.—J. C. C. Crawford (second-class honou and scholarship), M. H. Adams, H. C. Armstrong, J. J. Be Marion E. Buchanan, H. J. Goldring, J. G. Lord, J. S. McCorma and T. H. L. Montgomery.

University of Edinburgh.

On Dec. 19th, the following degrees and diplomas we conferred:—

M.D.—§*R. D. Aitken, §*L. J. Davis, I. B. Ewart, †W. M Ford-Robertson, William Goldie, *Laura M. Ligertwood, §J. F Loots, D. P. MacIver, †Milan Sokolovitch, §Joseph Weinstei ‡J. H. H. Williams, and Morris Witkin.

M.B.—J. W. Bridgman, R. O. Cairns, J. G. Craven, §W. I de Faria, William Finlay, K. N. Flint, M. El Gazayerli, F. M Gordon, I. D. Grant (with honours), M. B. Griffith, J. R. Hop J. E. Ilbery, Edward Joffe, T. M. Khan, R. S. Kirk, Gerard Lan E. H. Langschmidt, Amelia N. Laws, Joseph Levin, B. P. Lubb D. M. Lyon, A. P. M'Ara, D. C. MacGilchrist, D. J. MacRa C. L. Maingay, H. C. Maingay, D. H. Malherbe, R. A. Mitche D. S. Napier, §W. G. Pennington, W. M. Phinney, C. M. Ros Nathan Shapiro, W. S. Shaw, Edith Simpson, Harris Stang David Stern, D. W. Taylor, Gertrude J. K. Turner, R. A Turner, I. D. C. Veitch, F. A. Viapree, C. B. Watson, and E. S Wyder.

D.P.H.—C. P. Beattie, M.A., M.B., Ch.B.

The Ellis Prize in Physiology was conferred on W. A. Bain.

* Commended for thesis. † Highly commended for thesi
‡ Awarded Gold Medal for thesis. § In absentia.

University of Liverpool.

Dr. R. Stopford Taylor has been appointed lecturer i dermatology in succession to the late Dr. R. W. Mackenna

University of Durham.

On Dec. 20th, 1930, the following degrees and diplomas were conferred:—

M.D., for Practitioners of 15 years' standing.—W. S. O'Loughlin.

M.B., B.S.—A. G. Craven, William Hinds, T. E. C. Hurley, Kathleen N. W. Kearney, Gwendoline M. Langham-Hobart, J. T. Mani, and W. D. M. Millar.

B.Hy. and D.P.H.—Anne Fairweather, J. C. Hall, and Edward Porteus.

University of St. Andrews.

Dr. David Lennox has been appointed reader in forensic medicine, Dr. W. L. Burgess reader in public health, Dr. G. H. S. Milln lecturer in radiology and electrical therapeutics, and Dr. James Ferguson a tutor in anæsthetics

Poplar Hospital for Accidents.

It is proposed to provide a new out-patients' department at a cost of £30,000. In 1929 there were 127,000 out-patients.

National Institute of Industrial Psychology.

Under the auspices of this institute three public lectures on Muscular Work and Fatigue will be given by Dr. G. P. Crowden at the London School of Economics, Houghton-street, Aldwych, W.C., at 6 P.M. on Wednesdays, Jan. 21st, 28th, and Feb. 4th. Admission without ticket.

Nordhoff-Jung Cancer Prize.

The Dr. Sophie A. Nordhoff-Jung cancer prize for the best work of recent years in the field of cancer research has been conferred on Dr. Alexis Carrel, of the Rockefeller Institute for Medical Research, New York, in recognition of services to surgery by his development of tissue cultivation and his application of this method to the solution of the problems of pathological growth. The commission which made the award was composed of Professors Borst, Döderlein, von Romberg, and Sauerbruch.

Royal Institute of Public Health.

This institute will hold its annual congress over Whitsuntide (May 19th to 24th) at Frankfurt, with visits to Homburg, Wiesbaden, Nauheim, Heidelberg, and Kreuznach, and tickets may now be had from the hon. secretaries at 37, Russell-square, London, W.C. 1. Arrangements for travel and accommodation, which are offered at reduced rates, are in the hands of Sir Henry Lunn, Ltd., Endsleigh-gardens, Euston, W.C. 1, to whom application should be made.

International Illumination Congress.

This congress holds its ninth meeting next September in Great Britain under the presidency of Mr. Clifford Paterson. The congress proper will meet from Sept. 2nd to 12th, while the technical committees of the International Commission on Illumination will have their sessions at Cambridge from the 13th to the 19th. The subjects of discussion are likely to include the illumination of factories, offices, private houses and museums, and laboratory technique. The honorary general secretary is Colonel C. H. S. Evans, the Illuminating Engineering Society, 32, Victoria-street, London, S.W. 1.

Medical Society of London.

The syllabus for the second half of the 158th session gives the subjects chosen for six alternate Monday evenings, beginning Jan. 12th, which is a pathological meeting. On Jan. 26th Dr. E. P. Cumberbatch will open a discussion on the medical and surgical uses of diathermy; on Feb. 9th Dr. I. W. Macgill a discussion on the choice of anæsthetic; on Feb. 23rd Mr. A. Dickson Wright a discussion on the treatment of indolent ulcers of the leg; on March 9th Lord Dawson a discussion on the treatment of pneumonia; on March 23rd Dr. H. A. Harris and Dr. H. H. Mills a discussion on growth in children, clinical, radiological, and histological. Three Lettsomian lectures will be given by Dr. J. W. McNee on Feb. 16th, 25th, and March 4th, his subject being the spleen, its structure, functions, and diseases. Sir John Rose Bradford, P.R.C.P., will deliver the annual oration on May 11th.

Birmingham Hospital Centre Scheme.

Sir Charles Grant Robertson, chairman of the Incorporated Birmingham Hospitals Centre, has issued a statement reviewing the work so far accomplished, and explaining various features of the scheme. The city's response to the appeal for money he describes as "splendid," £584,000 towards the £1,250,000 required having been given since April last. When, the chairman says, the project is completed as planned "Birmingham will have something which no other British city has got." As to the Medical School, which is an integral part of the scheme, it is explained that "three important professors of the Medical Faculty" went to the United States last month as guests of the Rockefeller Foundation to study the design and arrangements of the newest and most important medical schools, and that upon their return early in January this part of the scheme will be actively taken up.

Medical Society of Individual Psychology.

Dr. Alfred Adler, of Vienna, will give an address at a meeting of this society to be held at the rooms of the Medical Society of London, 11, Chandos-street, W., at 8.30 P.M. on Friday, Jan. 16th. Members of the medical profession will be admitted on presentation of their visiting cards.

Extension of Horsham Hospital.

Lady Leconfield recently opened a new children's ward containing ten beds. The cost, including the provision of sun rooms for both women's and children's wards, has been £8000.

New Wing of Spilsby Hospital.

Lord Ancaster recently opened a new wing at this hospital, which has been given by Mr. J. W. Ramsden, of Hareby House, Spilsby, in memory of his father.

Post-graduate Courses in Berlin.

International post-graduate courses will be held in Berlin in March and April, including instruction in pathology, radiology, and surgery. Further courses on thoracic surgery, urology, physical and dietetic treatment, and other subjects will take place in October. Particulars may be had from the information bureau of the Kaiserin Friedrich-Haus, Luisenplatz 2, Berlin, N.W. 6.

Hospital Sunday Fund.

At the annual meeting of this Fund it was reported that the past year's collection amounted to £80,090, a reduction of £5109, and that for the last four years there has been a falling off not only in the receipts but in the number of collections. Donations produced £11,373 (a heavy drop), and the late Mr. George Herring's estate yielded £28,808, a small increase. The working expenses amounted to 4·57 per cent.

Birmingham Dental Students' Society.

The annual dinner of this Society was held at the Queen's Hotel on Dec. 13th, 1930, with Mr. A. G. Clendinnen, the President, in the chair. The President of the Birmingham Dental Hospital proposed the toast of the Society, and the Dean of the Hospital, in replying, stated that he only hoped the Birmingham Dental School would be moved in the near future to the new hospital centre at Edgbaston.

Sweepstakes for Hospitals.

The Committee, which lately sent out a questionaire to test public opinion on the desirability of sweepstakes for hospitals (see THE LANCET, 1930, ii., 1215), reports that more than 90 per cent. of the replies are favourable. Sir Gordon Campbell, the Chairman of the committee, states that he will make no move in the matter unless sweepstakes are legalised in this country, for he deems it undesirable to manage them from abroad, as has been proposed.

Glasgow Eye Infirmary.

For the first time since this Institution was founded in 1824 a public appeal is being made for the extension of accommodation, which the President, Sir M. W. Montgomery, describes as "hopelessly inadequate." In 1929 there were nearly 2000 in-patients and 32,000 new out-patients. The extension, which will cost £25,000, will include two new wards, additional out-patient accommodation, two large lecture rooms, consulting rooms, a new pathological section, bedroom accommodation for nurses, and verandahs to the children's wards.

Donations and Bequests.

The late Mr. T. Percy Legg, C.M.G., F.R.C.S., of Harley-street, W., who left £65,388, with net personalty £62,957, bequeathed his surgical instruments and microscope, medical and surgical books, and £200 for prizes for surgery to King's College Hospital Medical School; £100 each to King's College Medical School Clubs and Societies Union and King's College Hospital; and on the death of the survivor of certain specified persons, £1000 each to Epsom College, the Royal Medical Benevolent Fund, the Medical Society of London, and the Royal College of Surgeons, London; and the ultimate residue as to one-third to King's College Hospital and two-thirds to King's College Hospital Medical School. But should the hospital and medical school after the date of his will have admitted or continue to admit women medical students, beyond those already admitted, or if the hospital and medical school shall be supported or maintained by the State, then the ultimate residue of his property is to go to such charitable institutions or objects in England as the executors in their absolute discretion may select.—The Dundee Royal Infirmary has received a cheque for £100,000 from the trustees of the late Mrs. Marryat.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Jan. 6th.—8 P.M., Tropical Diseases. Paper: Colonel S. L. Brug (Batavia): Filariasis in the Dutch East Indies.

Wednesday.—5 P.M., History of Medicine. 8.30 P.M., Surgery. Pathological Evening: Specimens: Mr. A. E. Roche: Innocent Polyp of the Iliac Colon in a Woman of 64. Mr. H. A. B. Whitelocke: Retroperitoneal Sarcoma. Mr. John Everidge: X Ray Photographs and Lantern Slides of Intravenous Pyelography. Sir Lenthal Cheatle: Microscopical Appearances of Interstitially Radiated Tissues. Mr. Cecil P. G. Wakeley: Sarcoma of the Jejunum. Sarcoma of the Kidney in a Child. Teratoma of the Kidney in a Child. Other specimens will also be shown.

Thursday.—8.30 P.M., Neurology. Papers: Dr. J. Purdon Martin: Chronic Subdural Hæmatoma. Dr. E. Arnold Carmichael: The Ætiology of Disseminated Sclerosis: Critical Observations on Recent Work, with especial reference to Spherula Insularis.

Friday.—8.30 P.M., Ophthalmology. Cases: Mr. Norman Fleming: Flap Extraction, With Cinematograph. Mr. R. Foster Moore: Bilateral Cataract from X Ray Exposure. Other cases will be shown.

HARVEIAN SOCIETY OF LONDON.

Thursday, Jan. 8th.—8.30 P.M. (at 11, Chandos-street, W.), Annual General Meeting.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Friday Jan. 9th.—8.30 P.M. (at the West London Hospital, Hammersmith), Discussion on Malignant Diseases of the Large Intestine. Opener: Mr. G. Gordon-Taylor.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

Friday, Jan. 9th.—8.45 P.M. (at the Miller General Hospital Greenwich-road, S.E.), Clinical Evening.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Jan. 5th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

Wednesday.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations.

Friday.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Children's Diseases Clinics. Operations.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Friday, Jan. 9th.—4 P.M., Mr. Gill-Carey: Rhinological Aspects of Asthma.

ST. JOHN'S HOSPITAL, Morden-hill, Lewisham.

Monday, Jan. 5th.—4.30 P.M., Dr. John Gibbens: Diseases of Infancy and Childhood.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

Thursday, Jan. 8th.—9 P.M., Dr. E. Mapother: Alcoholism.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.

Thursday, Jan. 8th.—5 P.M., Mr. R. C. Brown: Cause and Treatment of Delay in the First Stage.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, Jan. 6th.—5 P.M., Dr. J. E. M. Wigley: Erythema Multiforme.

Thursday.—5 P.M., Dr. I. Muende: Pathology Demonstration.

Vacancies

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Jun. Asst. Surgeon.

All Saints' Hospital, 91, Finchley-road, N.W.—H.S. At rate of £150.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.

Bath. Royal Mineral Water Hospital.—Surgeon.

Blackburn Royal Infirmary.—Res. H.P. £175.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.

Bolton, Townleys Hospital, Farnworth.—Asst. M.O. £225.

Brighton, Royal Sussex County Hospital.—H.S. £150.

Brighton, Sanatorium and Infectious Disease Hospital.—Jun. Res. M.O. At rate of £150.

Bury St. Edmunds, West Suffolk General Hospital.—Jun. Res. M.O. £150.

Cambridge, Papworth Village Settlement.—H.P. At rate of £100.

Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—Sen. and Jun. H.S. £120 and £100 respectively.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. 1st Assts. for Out-patient's Dept.

Dunedin, New Zealand, Otago Hospital Board.—Radio-Therapeutist. £1000.

Ealing, King Edward Memorial Hospital.—Sen. H.S. Also Jun. H.S. £150.

Edinburgh, Elsie Inglis Memorial Maternity Hospital, Spring Gardens.—Jun. H.S.

Edinburgh Hospital for Women and Children, Whitehouse Loan.—H.P.

Exeter, Royal Devon and Exeter Hospital.—H.P. At rate of £150.

Finsbury Borough Council.—Asst. M.O.H. £750.

Golden Square Throat, Nose, and Ear Hosp., W.—Hon. Anæs.

Hampstead General and North West London Hospital, Out-Patient Dept., Bayham-street, Camden Town.—Cas. Surg. O. At rate of £100.

Harrogate Infirmary.—Jun. H.S. At rate of £125.

Harrow Hospital.—Radiologist. £100.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. At rate of £50.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Asst. Surgeon.

Huddersfield Royal Infirmary.—H.S.'s. At rate of £150.

Hull Royal Infirmary, Sutton Branch.—H.P. At rate of £160.

Leeds Hospital for Women.—H.S. At rate of £50.

Leeds University.—Lecturer in Pathology, also Pathologist to St. James's Hospital. £750.

Leicester, City Isolation Hospital and Sanatorium, Groby-road.—Jun. Asst. M.O. £300.

Leicester, City Mental Hospital, Humberstone.—2nd Asst. M.O. £350.

Leigh Infirmary, Lancashire.—Res. H.S. At rate of £150.

Lewisham Metropolitan Borough.—Asst. M.O.H. and Sen. Maternity and Child Welfare Officer. £750.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, David Lewis Northern Hospital.—Two Hon. M.O.'s for Ear, Nose, and Throat and Dermatological Departments.

Liverpool, Mill Road Infirmary.—Res. Asst. M.O. £200.

L.C.C.—Temporary Asst. M.O.'s. 30*s.* per session.

Maidstone, West Kent General Hospital.—H.S. £220.

Manchester, St. Mary's Hospitals, Whitworth-street and Whitworth Park.—Four H.S.'s. Each at rate of £50.

Mansfield, Notts, Harlow Woods, Orthopædic Hospital.—Res. Surg. O. £275.

Margate, Royal Sea Bathing Hospital, &c.—H.S. At rate of £200.

Middlesex C.C.—Dist. M.O. for Tottenham. £180. Also Public Vaccinator.

Northern Rhodesia.—Three M.O.'s. Each £600.

Nottingham Children's Hospital.—Res. H.S. At rate of £150.

Nottingham General Dispensary.—Res. Surgeon. £250.

Nottingham General Hospital.—H.S. At rate of £150. Also Sen. Cas. O. At rate of £200.

Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.

Poplar Hospital for Accidents, East India Dock-road, E.—Sec Res. O. £175.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, N. Kensington, W.—H.S. At rate of £100.

Rotherham Hospital.—H.P. £180.

Royal Free Hospital, Gray's Inn-road, W.C.—Gynæcological Reg. £100.

Royal Northern Hospital, Holloway, N.—2nd H.P. At rate of £70.

St. Mary's Hospital for Women and Children, Plaistow, E.—Surgeon in Charge of X ray Dept. £100.

Sheffield, Jessop Hospital for Women.—Three Asst. H.S.'s. Each at rate of £100.

Sheffield Royal Infirmary.—H.P., H.S., Asst. Aural and Ophth. H.S. Also Asst. Cas. O. All at rate of £80.

Sheffield University and Royal Infirmary.—Asst. Pathologist and Demonstrator of Pathology. £500.

Southampton, Royal South Hants and Southampton Hospital.—Hon. Clin. Asst. Anæsthetist.

South India Missionary Hospital.—Medical Woman.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.P. and H.S. Each at rate of £100.

Warrington Infirmary and Dispensary.—Sen. and Jun. H.S £225 and £175 respectively.

West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Jun. H.P. At rate of £100.

Wolverhampton, Royal Hospital.—Cas. O. and Res. Anæsthetist. At rate of £125.

Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.

York Dispensary.—Res. M.O. £175.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Havant (Hants).

Births, Marriages, and Deaths

BIRTHS.

Couchman.—On Dec. 21st, 1930, at Upton-on-Severn, the wife of Hugh J. Couchman, M.B., of a daughter.

Paul.—On Christmas Day, 1930, at Queen Alexandra Hospital, Cosham, the wife of D. H. Paul, M.D., of a daughter.

Price.—On Dec. 22nd, 1930, at "Lawnbank," Grove-road, Sutton, Surrey, to Dorothy Price, M.B., B.Ch., wife of V. R. Price—a son.

DEATHS.

Adams.—On Dec. 28th, 1930, at Balernock, Shandon, Dumbartonshire, James Alexander Adams, M.D., F.R.F.P.S.G., V.D., aged 73.

Hodgson.—On Dec. 19th, 1930, Amy Hodgson, M.D., M.R.C.P., D.P.H., aged 45 years.

Wilson.—On Dec. 23rd, 1930, suddenly, at Braeside, Bardsey, Yorks, Hector Maclean Wilson, M.D., late Chief Inspector W.R. of Yorks Rivers Board, aged 72.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

SOME LESSONS OF THE EPIDEMIC OF VENEREAL DISEASE

(1914–1924).

BY JAMES H. SEQUEIRA, M.D., F.R.C.P. LOND., F.R.C.S. ENG.,

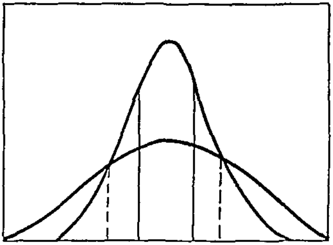
CONSULTING PHYSICIAN TO THE SKIN DEPARTMENT, LONDON HOSPITAL.

I WAS recently reviewing the report of the conference on ulcus molle, which took place at the Annual Meeting of Dermatologists at Strasbourg in 1928, and was impressed by the copious statistics presented by Dr. Dekeyser, secretary of the Belgian Dermatological Society.[1] The object of these figures was to show the relative frequency of soft sore, syphilis, and gonorrhœa. They were obtained from official sources in 16 European countries, from the United States, and from British Dominions. There are 36 tables in all. There are unavoidable blanks because several countries can give no information as to the incidence of the venereal diseases in the civil population. But there are numerous valuable reports from the military and naval services. Unfortunately, some of the belligerent States were unable to supply figures for the period of hostilities, but their records of the decline of the epidemic are useful to compare with other data.

It occurred to me that by constructing graphs representing these figures I might learn something as to the factors which influenced the diminution of venereal disease from 1920 to 1924. As I found, incidentally, that some of the details collected from so wide an area confirmed other observations, I venture to believe that the charts give a reasonably accurate presentation of the facts.

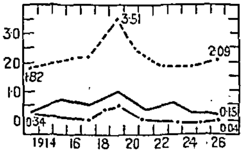
The authorities responsible for the therapeutic measures taken to combat venereal disease, and the *organisations which support them by propaganda, must* have been gratified by an annotation appearing in THE LANCET last April,[2] in which it was stated that "the gradual but steady decline of syphilis in European countries since the late war must be attributed to the intensive Government campaign against the disease." But three weeks later another annotation[3] candidly confesses that "the encouraging results mentioned in April are somewhat discounted by the story of the behaviour of syphilis in Helsingfors and all Finland." These remarks are based upon the report of Dr. Wilén. This authority, after an exhaustive study of the conditions obtaining in the area under his observation, says: "It would seem that salvarsan treatment is unable to counteract the periodic increase of the disease to the extent hoped for." Dr. Wilén supports the thesis of Buschke, Gumpert, and Langer, who, in 1927, expressed doubts about the modern treatment of syphilis being the chief factor in its periodic decline. These writers considered that the "incidence of venereal disease is mainly determined by economic and social factors, and that the explanation for the fluctuation in their frequency is to be found (or hidden) in the term 'genius epidemicus.'"

FIG. 1.



Two types of curve similar to that of the incidence of cases in certain epidemics (after Singer).

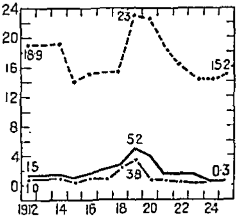
FIG. 2.



Sweden (civil population). Incidence of venereal diseases per 1000 inhabitants. In this and subsequent figures the three diseases are represented as follows:—

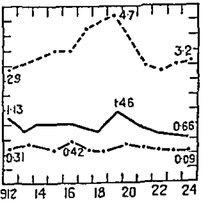
- - - - - - - - Acute gonorrhœa.
——————— Syphilis (primary and secondary).
—·—·— Soft chancre.

FIG. 3.



Sweden (army) per 1000 men.

FIG. 4.



Denmark (civil population) per 1000 inhabitants.

Fierlinger,[4] in the League of Nations Report, doubts whether there is a real decrease in the incidence of syphilis and "whether the treatment has the value claimed for it." There is no question as to *the decline from 1920 to 1924, as the following graphs* show, so that one must assume that Dr. Fierlinger was referring to reports of later declines. Dr. Dewar, at the Imperial Social Hygiene Congress,[5] while noting the steady fall in the incidence of syphilis from 1920 to about 1926, stated that "it is believed that for some unknown reason there has been an increase in the prevalence of this disease." Local increases have been recorded by French observers during 1926, and they have attributed them to the which explains certain types of epidemic. Neither, on similar grounds, can I see any evidence to indicate a "genius epidemicus" as suggested by the authors quoted above.

(3) That the variations in the reservoirs of infection in different areas and the relative immunity of the population concerned appear to have little influence on the epidemic status.

(4) That the transmission factor was the prime agent. It is difficult to say whether economic conditions played any part. It is evident that during the war years and immediately after there was an enormous outpouring of money, and this undoubtedly raised the spending power of the communities. It is also certain that, coincident with the decline in the incidence of the venereal diseases, there has been a fall in material prosperity.

(6) That it is inconceivable that the remarkable correspondence in the duration of the three curves of decline can be the result of treatment, which differs so completely both in principle and character in the three diseases. While earnestly supporting all efforts to bring the infected under treatment at the earliest possible date, and the employment of every means available to shorten the period of infectivity and to counteract the deleterious effects of these diseases, we must not claim too much. We must not delude ourselves with the idea that measures, however beneficial to the individual, can produce a world-wide decline in the incidence of three different types of disease. The rise and fall of epidemics depend upon much bigger factors, and so far as I am aware no epidemic disease has been removed by treatment, however intensive.

Finally, it would appear that in any future contingency of this type the efforts of the sanitarian must be concentrated upon the transmission factor. The value of such measures as the *cordon sanitaire*, the provision of prophylactics, and the immediate disinfection of suspected contacts, was evident in the comparatively few instances in which they were employed efficiently in the late war.

ANÆSTHESIA IN MENTAL CASES.

THE necessity for paying due regard to the mental state of a patient before operation is rightly receiving more and more attention. As H. Kilan has written, "many patients squander their physical and psychic energies through anxiety over the operation and not from serious strain which the operation itself represents." And when we come to patients who are actually mentally unstable these considerations become paramount. The harm, even fatal harm, that can be done to persons of this kind by an administration that does not exterminate fear and that does promote excitement is undoubted, but is too often underestimated. Hysterical, neurotic, borderline, and actually insane persons belong to this group for whom the utmost care in choice and giving of anæsthetics is desirable, and S. J. Turel[1] strongly recommends colonic anæsthesia for them. There is no doubt that the method has exceptional advantages, for it can be used without causing the patient the slightest psychic disturbance, indeed, without his knowing that an anæsthetic is to be given or an operation performed. Turel's experience has been with colonic ether, and he makes only slight reference to avertin which is likely to be of increasing utility in the situations which he discusses. In practice the actually insane are generally found fairly easy to deal with. It is in the highly emotional and the psychoneurotic that so much care is needed if injury is to be avoided.

THE LATE DR. WILLIAM MACLEAN.

Dr. G. Lissant Cox sends the following pers note about Dr. William Maclean, medical officer of health for Ross and Cromarty, whose obituar notice appeared in our issue of Dec. 20th, 1930:—"Maclean was a remarkable man, and his death i deplored by all his friends. I met him first at th Loch Maree food poisoning (botulism) traged Many medical men were there; alone amongst them Maclean recognised symptoms corresponding to an outbreak of food poisoning described by Van Ermengem. This will give some indication of his ability, and the resources of his splendid library. But Maclean was not learned only in medicine. The classics, ancient and modern, archæology, field botany, and geology were part of the man himself. He was one of those rare persons who inspire not only complete confidence but an indefinable sense of charm. His Scotch humour was a pure joy, and sparkled the more there should be a solitary Englishman amongst many Scots. A first-rate fisherman, too, he was; whatever he touched he adorned. Scotland is indeed poorer by his death."

NEW PREPARATIONS.

EPINALIN (Burroughs Wellcome and Co., Snow Hill, London).—This solution of "Wellcome" Brand Adrenalin and "Wellcome" Brand Ephedrine Sulphate has been recently introduced for applicati to the pharynx and nose by means of an atomis Each cubic centimetre contains adrenalin 0·0001 (=1 in 10,000), and ephedrine sulphate 0·02 g. (= in 50). The powerful but relatively transient acti of adrenalin is followed by the prolonged action ephedrine, and the drug has been found valuable a nasal spray in asthma and hay-fever, in engorged co ditions to shrink the nasal mucosa, and to aid drain in sinus suppuration. Epinalin may also used, preparatory to rhinoscopy, as a swab to turbinates, or to tooth sockets, and also after ton lectomy. It is issued in bottles of 10 c.cm. a 25 c.cm.

SIONON (Bayer Products, Ltd., 19, St. Dunstan hill, London) is a carbohydrate (a gluco-hexite) the diabetic, the calorific value of which is said be practically equivalent to that of glucose, 100 of Sionon equalling 390 calories. It is a white odourl crystalline powder with a sweetish taste, and can used in the preparation of cooked foods without any way affecting its composition. When cooked exhibits a binding action similar to that of sug The account of the drug which is distributed wi the preparation sets out its action and mode of us and it is well to note that any suggestion is disclaim that Sionon can influence the cause of diabetes, as exercises no material effect on insulin formatio Nevertheless it has proved its utility in treatme to the satisfaction of some users. It is sold in ti of 500 g. The contents weigh about 2 lb., whic is more than 500 g., and the substance should administered in daily quantities of 30–80 g. (1–2½ oz. which should be taken at intervals, as otherwis it may be too relaxing.

THE address of the Central Council for Distric Nursing in London is now 12, Whitehall, S.W. (near the Admiralty Arch). Tel.: Gerrard 1610.

ADDRESSES AND ORIGINAL ARTICLES

CŒLIAC DISEASE.*

BY LEONARD G. PARSONS, M.D., F.R.C.P. LOND.,
PHYSICIAN TO THE CHILDREN'S AND GENERAL HOSPITAL, BIRMINGHAM; PROFESSOR OF DISEASES OF CHILDREN IN THE UNIVERSITY OF BIRMINGHAM.

IN the year 1725 what was probably the first case of cœliac disease was shown to the Society for Children's Diseases in Jena, but the first description of the disorder was in a short paper by Samuel Gee in the year 1888 "On the Cœliac Affection." This paper, comprising but three pages in the St. Bartholomew's Hospital Reports, is a model of clinical observation and, as far as the description of the digestive and many of the general symptoms is concerned, very little has been added to it by later writers. Following on this communication a few cases were reported by R. A. Gibbons and by W. B. Cheadle (under the title of Acholia) and, in all probability, some of the cases of pancreatic infantilism described by Byrom Bramwell were examples of cœliac disease. The next important contribution was made by C. A. Herter in America in 1908, who in his monograph "Infantilism from Chronic Intestinal Infection" has been accused of rediscovering the disease. Within recent years the writings of G. F. Still, R. Miller, H. Lehndorff, and H. Mauntner have led to a wider recognition of the disorder. On the Continent of Europe the condition is frequently called Heubner-Herter disease, but there can be no doubt that if any one name is attached to this disease it should surely be that of Gee.

Clinical Features.

This disease which occurs in all grades of society is more common in girls than in boys, and has been observed in one of homologous twins. The disease has never been seen in a child at the breast. The onset is usually insidious during the age-period of nine months to two years. Associated as that age-period is with dietetic changes and teething it is not to be wondered at that the earliest digestive symptoms of the disorder are usually ascribed to such causes, and it is often only after the bowel disorder and failure to thrive has been present for some time that the correct diagnosis is made or even that medical advice is sought. In the early stages of the disease diagnosis is almost impossible; indeed it is often not made until the complete clinical picture has developed, and thus the cause of the illness frequently remains undiagnosed until the child is five or six years of age. Careful inquiry into the history of such cases will nevertheless often reveal the fact that digestive disturbances have been present for a long time, possibly for years. Occasionally the onset is apparently an abrupt one, and then a few days after the onset of an acute attack of diarrhœa and vomiting the stools are noticed to be large and pale. The characteristics of the fully developed case are: (1) the passage of large, pale, and offensive stools containing considerable amounts of fat; (2) wasting—and stunting of growth amounting to infantilism—chiefly due to absence of stored fat; (3) abdominal distension; (4) anorexia and certain other nervous symptoms; and perhaps (5) the presence of deficiency symptoms.

CHARACTER OF THE FÆCES.

The fæces furnish the key to the diagnosis of cœliac disease, and there is no better description of them than that contained in Gee's paper: "Signs of the disease are yielded by the fæces, being loose, not formed, but not watery; more bulky than the food taken would seem to account for; pale in colour as if devoid of bile; yeasty, frothy, an appearance probably due to fermentation; stinking, stench often very great. The hue is somewhile more yellow, otherwhile more drab." During the long drawn-out course of cœliac disease there are many ups and downs, and for periods the stool may be quite formed and even coloured but at other times the typical stools so aptly described by Gee are present, although under adequate treatment they are not so frequently seen as in the untreated case. Miller holds the view that certain cases are characterised throughout their whole course by the absence of diarrhœa and speaks of a non-diarrhœal type of cœliac disease, but it would appear that these types only indicate a difference in severity. In the diarrhœal periods more free fatty acid is present in the stool whereas soaps predominate in the more or less formed stools of the non-diarrhœal periods.

The number of stools passed each day varies thus: in the non-diarrhœal phases there may be one or two a day, whereas in the diarrhœal phases two to three is a very common number, although sometimes there may be five or six. The stool is large and when loose contains a high percentage of water, a point which continental writers think of very great importance. Some of the marked vagaries of the patient's weight chart may depend upon the weight of the stools since the total weight of stool passed in 24 hours may be one pound. Not only is there excess of water but on ordinary diet there is always, even in the non-diarrhœal periods, a considerably greater amount of solid matter than in a normal stool and of this a large proportion is fat. Fat should not form more than 25 per cent. of the dried fæces of a child taking an ordinary mixed diet, but in cœliac disease it usually forms from 40 to 60 and may even reach 80 per cent. The estimation of the percentage composition of the fæces is of the greatest importance in arriving at a diagnosis of cœliac disease, but it must always be correlated with the weight of the dried fæces since in all diarrhœal conditions the stool contains more fat than normal. A diagnosis of cœliac disease should not be made if the stool does not contain more than 2 g. of fat per day, but the amount of fat passed daily is usually very much greater than this and may reach 20 g. or even more. It is also advisable to estimate the amount of fat passed over a period of three to five days. In spite of this large proportion of fat in the stool the absorption of fat is often—particularly in the non-diarrhœal periods—surprisingly high. For instance in a child whose dried fæces showed 42·1 per cent. of fat, 83·5 per cent. of the total fat intake was absorbed. The significance of this may perhaps be better understood when it is remembered that the normal child absorbs about 95 and children suffering from biliary atresia an average of 30 per cent. of their fat intake. Further within certain limits an increase in the fat intake produces an increase in fat absorption. This occurs when one case is compared with another and also in the same case, and is probably one of the reasons why occasionally children suffering from cœliac disease have done well on cod-liver oil. Nevertheless a high or even a normal fat intake usually cannot be maintained for any length of time because an increase in the number, size, and offensiveness of the stools results.

---

* An address delivered before the Ulster Medical Society on Nov. 13th, 1930.

In spite of this steatorrhœa the fat in the stools is well split, and the neutral fat does not form more than 25 per cent. of the total fat, and as a result of the great loss of fat in the stools there is marked demineralisation and in particular a considerable loss of calcium and phosphorus. Nitrogen absorption, on the other hand, by balance experiments appears to be normal.

The frothy appearance of the stool to which Gee refers is probably due to fermentation of carbohydrates.

WASTING.

Wasting, which becomes obvious as the disease develops and often reaches an extreme degree, is largely due to the absence of subcutaneous fat and is particularly noticeable in the gluteal and adductor regions. For some unknown reason the face often remains plump and rounded, and frequently there is quite a degree of colour in the cheeks so that almost a characteristic facies develops. If the child is clothed when first seen the degree of wasting revealed by undressing is indeed astounding, for these children "strip" badly. The wasting of the limbs contrasts markedly with the face as also does the distended abdomen with the atrophied buttocks. Indeed so striking is the latter that Miller has referred to it as the "gluteal sign."

The degree of wasting may perhaps be realised when it is stated that a child of 2 years old may weigh from 14 to 16 lb. instead of a normal 28 lb. The progress of the case shows a weight chart with many ups and downs, the variations being due to some extent to the presence or absence of large amounts of fæcal material in the bowel or to varying degrees of water in the tissues (hydrolability), and thus the net result of many weeks of treatment may only be represented by gain in weight of one or two pounds. The importance of wasting as a symptom may perhaps be emphasised by another quotation from Gee, "To diarrhœa alba add emaciation and cachexia and we have a complete picture of the disease."

Associated with the wasting is a marked degree of muscular hypotonia and a diminution of the rate of growth and physical development, with the result that as the child becomes older it is seen to be stunted, and a child of 9 may appear to be four or five years younger than its actual age. Unless appropriate treatment is instituted, this infantilism becomes more and more marked as the child grows older. The most extreme case in my experience was a girl whose height when 17 years old was no greater than a normal child of 4 years of age, and who had such extreme delay in dentition that none of her permanent teeth had erupted. As a rule dentition is delayed, but not to this extreme degree, and in some cases the enamel is badly formed.

Abdominal distension is another very obvious and characteristic symptom. It is rendered the more striking by the wasting of the gluteal region, and its presence leads frequently to the mistaken diagnosis of tuberculous peritonitis. The distension varies somewhat in degree depending on the state and contents of the bowels, for it has been demonstrated by radiographic examination that this symptom is due to flatulent distension of the intestine, particularly the colon. Hypotonia of the abdominal wall is also a factor in the distension.

NERVOUS SYMPTOMS.

Anorexia may reach an extreme degree, but fortunately on the other hand some of these children will suffer the infliction of protein skimmed milk as their sole dietary for long periods. The appetite is, however, always markedly capricious at some periods of the illness.

The behaviour characteristics of these patients are most interesting. Their intelligence is normal although the education of the older children naturally has suffered; the latter often appear to be rather precocious chiefly because their infantilism causes them to be treated as much younger than their actual age. In their periods of improvement the subjects of cœliac disease are most attractive, although perhaps more easily moved to tears than a normal child and usually somewhat spoilt, but in the diarrhœal period they are irritable and passionate and are as moody and capricious as their appetites; nothing pleases them, and their misery reaches a degree which makes them a trial to those who have charge of them and would lead one to suppose that it could not be the same child which was previously such a fascinating person. "When they are good they are very, very good, but when they are bad they are horrid."

There are not any definite signs of organic nervous disease. Sometimes the limbs are tender—a symptom to which Gee referred to as muscular tenderness—and this has been said to be due to peripheral neuritis. Such a diagnosis receives some support from the fact that the knee-jerks may be absent, but the probability is that the tenderness is due to scurvy.

A degree of anæmia of the secondary type, probably nutritional in origin, is usually present, and severe anæmia resembling that seen in sprue has been described in one or two cases.

DEFICIENCY SYMPTOMS.

A series of symptoms which are probably the result of vitamin deficiency may now be considered. Scurvy occurs in mild degree, being the result of the restricted dietary. Œdema is not infrequent, and occasionally free fluid can be demonstrated in the abdominal cavity, which adds yet another difficulty to the differentiation of cœliac disease from tuberculous peritonitis. This œdema is very similar to the nutritional or hunger œdema seen in marasmic infants, and it has been suggested that it is an infantile manifestation of beri-beri and due to absence of vitamin B. Recovery from this symptom may occur after adding ripe bananas which are rich in vitamin B to the diet.

It has been suggested that the stunting of growth is itself a "deficiency" symptom and due to deficiency of vitamin A or of a combination of vitamins. The liability to infections, particularly coryzas and the occurrence of parenteral infective diarrhœa, is more probably due to absence of vitamin A, but it is curious that what is usually regarded as the specific lesion of vitamin-A deficiency—xerophthalmia—is rarely seen, although cases have been reported by B. Schick.

The most interesting group of symptoms which call for discussion under this head are those concerned with the bones. Rickets occurs at two definite periods in cœliac disease—namely, in infancy and in the later years of childhood. It may occur at the ordinary age-incidence of rickets—i.e., 6 to 18 months—may heal and then reappear at from 5 to 7 years and reach an extreme degree. I have not observed this sequence in the same case although it has been reported by Lehman, but I have seen rickets at these two age-periods in different cases. The early rickets differs in no way from ordinary infantile rickets except that the cod-liver oil can rarely be used as a curative agent. The rickets, however, may heal as a result of the presence of cœliac disease, for this produces a partial starvation and arrest of growth, conditions which cure experimental rickets in rats. The bone itself is atrophic and fragile, in fact shows an osteoporosis, and gives a radiogram which to anyone who is familiar with the picture would itself suggest that the underlying condition was cœliac disease. Tracing chronologically then the order of events we may see: first, in infancy an osteoporotic bone with rickets; secondly, as the cœliac disease asserts itself more strongly, and stops growth, a stage occurs in which there is a fragile osteoporotic bone but no rickets, and if the cœliac disease has been present for two or three years there are frequently transverse lines in the metaphysis which indicate periods of complete arrest of growth; thirdly, at the age of 5 to 7 when growth is more rapid the bone is still osteoporotic and fragile, but rickets asserts itself again. As mentioned above, it is only rarely that all these stages are seen in the same child, usually the second and third stage only are seen; moreover, the occurrence of the third stage in any case indicates that treatment has been faulty.

The proof that these later bone changes are rachitic is based on (*a*) radiographic appearance, (*b*) blood chemistry, and (*c*) the results of treatment. The radiographic appearances are those of rickets, the blood shows low values for calcium and phosphorus, and treatment by ultra-violet irradiation or non-fatty preparations of vitamin D—e.g., irradiated ergosterol in solid form, cures the rickets and produces a normal blood chemistry. The underlying cause of the bone changes is deficient absorption of calcium and phosphorus, the result of non-absorption of fats and the fat-soluble vitamin D. Such a deficiency in fat-soluble vitamin D is obviously not improved by giving a "fat free" diet.

The activating cause of the rickets is, however, growth; as long as growth does not occur the child is able to supply sufficient calcium and phosphorus to calcify the rarefied bone, but when growth occurs and new bone has to be formed rapidly normal calcification becomes impossible. The usual manifestations of rickets are genu valgum and some enlargement of the epiphyses of the wrist, but the most intense degree of rickets may occur, so that the child shows multiple deformities, rosary, enlarged epiphyses, natiform skull, and multiple fractures of the long bones, and becomes quite unable to stand or walk.

The occurrence of late rickets in cœliac disease has been denied by W. McKim Marriott and others, but in Birmingham it is not infrequently seen. Further, the realisation of the possibility of its development during the rigid dieting which forms such an essential part in the treatment of cœliac disease is of the greatest importance, since appropriate preventive measures can then be instituted.

Another deficiency symptom that occurs from time to time in cœliac disease and which also depends on the presence of low blood calcium is manifest tetany. Donald Hunter has described a case of osteopathic steatorrhœa with tetany and dwarfism in a woman of 34 years of age who had intestinal symptoms and tetany from childhood, and which appears to be an example of cœliac disease persisting in adult life. This patient showed collections of opacities in the lens similar to those seen in post-operative tetany. Slit-lamp examination of several children with cœliac disease has, however, not revealed any opacities of the lens.

It is curious that whereas rickets is comparatively frequent in cœliac disease yet xerophthalmia is so rarely met with, and there is no adequate explanation of why these children can stand deficiency in vitamin A so much better than deficient absorption of vitamin D.

Prognosis.

Cœliac disease runs a long drawn-out course marked by many ups and downs. Even without any treatment it is possible for the patient to survive as a stunted feeble individual, since improvement usually occurs at puberty. Not infrequently, however, the child succumbs before that period from some intercurrent infection, although death from uncomplicated cœliac disease is relatively rare. Moreover, in spite of careful treatment, progress towards recovery is slow and intermittent and diarrhœa occurs from time to time, possibly from irregularities and premature changes in the diet, or from parenteral infections, but if treatment is carried out efficiently a cure can usually be promised. The length of time required to effect a cure varies in different individuals, even although the disease may appear to be of similar severity when treatment is started. In many cases in which recovery appears to have taken place the stools show rather more fat than the normal, whereas in others a complete clinical and "biochemical" recovery occurs. In some instances after puberty is established both "biochemical" and clinical recovery rapidly occur.

Increase in weight and height are good tests of the improvement of a case, but any definite retardation of growth always leaves its mark, and, although after recovery growth may be considerable, the child never reaches normal height. Fat is deposited in the subcutaneous tissues, and in some children for a few years after cure is complete the distribution of fat is very like that seen in mild examples of Fröhlich's syndrome, and the weight for height proportion is greater than in the normal child. The disease rarely persists into adult life, but the case reported by Hunter, and to which I have already referred, appears to be beyond criticism.

In arriving at the present-day conception of cœliac disease there have been four important landmarks. First, the stress laid by Gee on the intestinal symptoms—the diarrhœa alba; secondly, the insistence by Herter on infantilism as an outstanding symptom; thirdly, the success of a protein dietary in treatment; fourthly, the recognition of the presence of many symptoms of a deficiency disorder—e.g., tetany, scurvy, rickets, œdema.

Morbid Anatomy and Causation.

There is no known morbid anatomy of the disease and its cause is quite unknown. Post-mortem examinations are somewhat rare, and any abnormal appearances that have been observed in the course of such examinations are either due to secondary infections or to the result of malnutrition. There is no evidence of enteritis, a fact which disposes both of the theory that the disease is allied to sprue, as first suggested by Gee, and also of the view that it is a special form of chronic enteritis.

In chronic enteritis the stools do not have the characteristics of cœliac disease, and although there is an increased loss of fat in diarrhœa this loss is not so great as in cœliac disease in which, as a matter of but administration of carotene, a body closely related to vitamin A, is well worth a trial.

As to other forms of treatment rest in bed is of great importance in the early stages of the disease, and at any time if the disease is severe or if rickets is present. Care should be taken to prevent parenteral infections, and if the diarrhœa is severe periodic blood transfusions are of the greatest value and may prove the turning-point in a severe case. Gentle massage to the limbs is helpful, particularly during the period of confinement to bed. For the secondary anæmia liver extract may be tried, but the drug most likely to prove helpful is ferrum redactum in one-grain doses which, incidentally, is chiefly of value because of the copper present in it as an impurity. Other drugs are of little or no value in cœliac disease, and the administration of pancreatic extracts is based on an incorrect conception of the disease.

The treatment of cœliac disease is very tedious and often anxious, yet withal fascinating, because, by perseverance along the lines suggested, a complete invalid can be transformed into a useful member of child society, and at times even the bed-ridden can be made to "take up his bed and walk." Such success can, however, never be obtained without intelligent coöperation on the part of the parents and the expenditure of much care, thought, and anxiety on the part of both doctor and parents.

The original investigations to which reference has been made in this address have been carried out jointly with my colleagues, Dr. A. V. Neale and Dr. E. M. Hickmans, to whom, as well as the Medical Research Council, who have defrayed the expenses incurred, I am greatly indebted.

SOME CLINICAL CONDITIONS ASSOCIATED WITH ACHLORHYDRIA.*

By John F. Wilkinson, M.B., M.Sc.,
Ph.D. Manch., F.I.C.,
DIRECTOR OF THE LABORATORY FOR CLINICAL INVESTIGATIONS AND RESEARCH, MANCHESTER ROYAL INFIRMARY;

AND

T. H. Oliver, M.D. Manch., M.R.C.P. Lond.,
HON. ASSISTANT PHYSICIAN, MANCHESTER ROYAL INFIRMARY.

The association of achlorhydria with pernicious anæmia and subacute combined degeneration of the spinal cord is well recognised, but its presence in other conditions is not so widely appreciated. In infectious diseases its occurrence has been observed by many workers. Thus Van den Velden and Thaysen and Wegge noted it in typhoid fever; Frankl and Plaschkes found 25 per cent. with achlorhydria and 50 per cent. with hypochlorhydria after typhus, whilst of paratyphoid cases 50 per cent. had achlorhydria and 35 per cent. hypochlorhydria. Torning has seen achylia gastrica in 6 per cent. and hypo-acidity in 9 per cent. of 150 pulmonary tuberculous patients, whilst Permin showed that achlorhydria became more common as the disease progressed and was present in 75 per cent. of the advanced cases; similar observations have been made by Faber (1905) and by Faber and Lange and others. In malarial patients 26 per cent. have been shown to have an achlorhydria that frequently persisted throughout life (Guido). Achylia gastrica was also commonly found by Bloch after acute infections, such as influenza, pneumonia, and enteritis. The occurrence of achlorhydria or achylia gastrica after a variety of toxic or irritant factors has been discussed by workers in this country, notably Hurst, and in other countries by Faber and Lange, Faber (1920), Martius, Weinberg, Martinez, and many others.

Whether achlorhydria is congenital or acquired is a matter still in dispute. Martius noticed that a large proportion of young children had reduced gastric acidity, and considered this as evidence for a congenital occurrence. Jacobsen, however, found that many children with gastric symptoms did not show any pronounced tendency to achlorhydria, although it did occur amongst those with acute intestinal affections. Treatment and examination after recovery showed that some recovered normal gastric function while others did not. Similar results were obtained by Hertz, Chievitz, and Klementsohn. From an examination of normal infants, Marriott and Davidson, Babbott and others, and Davison, amongst others, found that gastric samples withdrawn at the height of digestion usually showed values of pH 3·0–pH 5·0, few cases falling below pH 3·0, but there was an increased acid-production with increased age. Since the healthy adult's gastric juice is approximately pH 1·2–1·4 (60–40 units of n/10 alkali), it will be seen to be of the order of a hundredfold to thousandsfold more acidic than was found in these normal infants.

It is possible that the gastric juice of such infants is not fully developed until later. This would be in harmony with the suggestion of Bauer that the persistence of the infantile glandular state means the under-development of the acid-secreting elements. The ease with which the gastric juice is influenced in infants by slight malaise or disease makes it difficult to interpret such results, as suggested by Faber.

Martius considered that chronic achylia gastrica was due to a congenital constitutional abnormality and was not secondary to a gastric atrophy, as put forward by Einhorn (1892). Faber (1920), however, thinks that it is due to a chronic gastritis of exogenous cause; whilst Schmidt believes that anomalies of innervation of the stomach will explain the dysfunction. Albu has explained it on the grounds of a congenital functional debility of the mucosa, but Disqué suggests a neurogenic factor leading to a functional depression of the mucosa.

It has been observed by several workers that the frequency of achlorhydria or hypo-acidity increases with age, and a variety of causes have been suggested—e.g., toxins, irritants, senile atrophy, and gross abuse of the stomach, as by insufficient mastication of the food, alcohol, &c. In this connexion, Seidélin found that 40 per cent. of working-class patients over 50 years of age and 67 per cent. over 67 years of age had absent or diminished secretion, whilst Dedichen observed anacidity in 66 per cent. of 99 healthy old people of 67 to 92 years of age. Keefer and Bloomfield, Faber (1927), and Gilford, have made similar observations whilst, on the other hand, Bell considers that hyperchlorhydria is also more common over 40 years of age. Vogelius found that cases of alcoholic gastritis with free acid in the gastric secretion showed achylia a few years later. Over 50 per cent. of these cases had gastritis, and improved in the early stages with treatment and abstinence from alcohol.

More recently, attention has been redirected by Langdon Brown to the importance of this association of achlorhydria with a variety of diseases. While Hurst (1929) has made similar observations and regards it as an ætiological factor in gastric carcinoma, Ley has observed achylia in patients over periods of many years and not noticed the development of cancer.

---

* From the Laboratory for Clinical Investigations and Research, Manchester Royal Infirmary.

Again, asthmatic patients frequently show a diminished or absent hydrochloric acid secretion, as recently emphasised by Bray, whilst the treatment of hay-fever with nitro-hydrochloric acid has been tried by Beckman for some years.

During the past two years we have been investigating certain types of cases in which the clinical condition has suggested an impairment of the gastric secretion. We have examined 100 cases by means of the fractional test-meal and have found a surprisingly large percentage with achylia gastrica or hypo-acidity. These may be considered conveniently in the following five groups:—

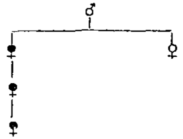
Gastrogenous Diarrhœa.

Group 1.—It has been known for a long time that a certain type of diarrhœa appears to bear some relationship to a deficient gastric acidity. This is the "gastrogenous diarrhœa" originally described by Einhorn (1898). Udaondo has cited a case in which a parent and two children, suffering from chronic diarrhœa, had achylia. More recently, Martinez has reported that he has seen two families with chronic diarrhœa associated with very marked nervous symptoms. In the first, a mother and four children had chronic diarrhœa and gastro-intestinal disturbances associated with achlorhydria, while five out of the 13 grandchildren also had achlorhydria. In the second family a mother and three daughters had chronic gastro-intestinal disturbances, together with achlorhydria. In both families there was an associated hysterical and very nervous temperament.

Studying 50 cases of mucous colitis, Bockus, Bank, and Wilkinson found 11 with hypo-acidity and two with achlorhydria; 32 of these cases were females. In a review of 425 consecutive cases of fractional gastric analysis Bell found 11 cases of chronic colitis (two with hypochlorhydria but none with achlorhydria) and 4 cases of diarrhœa (one with achlorhydria only). A similar statistical survey of 912 cases of an acidity or hypo-acidity by Hartman and Sager disclosed very few cases of chronic diarrhœa; there were 49 cases of achlorhydria without any symptoms or other diagnosis, whilst 245 were classed as functional nervous disease and presumably would include some cases of gastrogenous diarrhœa. Recently, Spriggs has reported that in 111 cases of functional disorders of the colon the gastric juice was super-acid in 41 per cent., sub-acid in 23 per cent., achlorhydric in 2 per cent. It is, of course, well known that colitis and progressive gastric hypo-acidity occur in sprue, while one of us (J. F. W.) has recently seen chronic diarrhœa and achylia in a pellagrin.

We ourselves have observed the remarkable regularity with which a persistent or recurrent diarrhœa existing over long periods has been associated with a deficient gastric secretion. This type of gastrogenous diarrhœa often appears to benefit by the exhibition of small doses (♏ v.–xv.) of hydrochloric acid (cf. Hurst (1929), Hunter, and Kantor and Sagal). Of greater importance, however, is the fact that there appears to be a very definite clinical picture associated with this "gastrogenous" diarrhœa, so much so that but rarely have we found the results of a fractional test-meal to be at variance with what we had suspected at the bedside. The recognition of this achlorhydric syndrome is of great practical importance as, in many instances, the simple remedy of giving adequate doses of dilute hydrochloric acid (♏ xxx.–lx.) leads to very striking therapeutic results.

In our first group of 53 cases the symptoms are mainly gastro-intestinal, the patient complaining of colicky pains, flatulence, and diarrhœa. This last symptom varies considerably in its severity; it may be intermittent and is sometimes only disclosed by questioning the patient. It is rarely sufficient to incapacitate, although occasionally there may be a history of blood or mucus in the stools. The history is usually a long one (3–20 years), while not infrequently a family history of looseness of the bowels may be obtained. One family in our series is worthy of especial mention in this respect. A man, invalided from the army in 1857 for persistent diarrhœa, his two daughters, a granddaughter, and a great-granddaughter all suffered from this condition. We were able to examine three members of the family, representing three generations, and in all of them we found achlorhydria.



○ = Chronic diarrhœa, gastric analysis not made.
● = Achylia associated with chronic diarrhœa.

Apart from the gastro-intestinal symptoms, these patients may complain of a lack of vitality and depression, and, as they are often highly neurotic, a diagnosis of nervous dyspepsia may be made. In some of the cases an intermittent soreness of the tongue may be complained of, and this may be a valuable guide in establishing the diagnosis.

The physical signs are few. There may be a slight secondary anæmia, and on abdominal examination the liver may be slightly enlarged, while tenderness can be elicited by deep palpation over the descending colon, and succussion sounds are common. The following is typical of the cases we are describing:—

A clerk, aged 36, consulted us complaining of an indigestion of many years' standing. He suffered from colicky pains across the abdomen and extreme flatulence, and gave a history of intermittent diarrhœa. During the war he was gassed and the diarrhœa was very severe; it has recurred from time to time since then. For two months before he was examined the diarrhœa had ceased, but the motions were irregular, the bowels usually being opened twice a day. There had never been any blood or mucus in the stool. He said that he was always tired, did not feel fit for his work, and that his ankles swelled at night. On questioning, he said that he had had occasional ulceration of his mouth during the past ten years.

On examination, he was pasty and unhealthy looking, the abdominal wall was flabby, and there was much splashing and gurgling on palpation. The liver could be felt about one inch from the costal margin. There were no other physical signs to be made out, and the only positive result obtained from clinical investigations was the gastric analysis, which showed complete achlorhydria.

He was given ♏ xxx. of acid. hydrochlor. dil. (B.P.) and pepsin, three times a day after meals, and immediately improved. A year later he reported himself to be very well; he had gained 1½ st. in weight and no longer suffered from gastro-intestinal symptoms.

Although in the majority of cases there is no danger to life, occasionally the achlorhydria may be associated with a much more serious condition and is probably the precursor of it. In one case, which has already been recorded (Susman and Oliver), an acute yellow atrophy of the liver followed the intense enteritis that had developed. In another case diabetes developed in a patient who gave a long history of gastro-intestinal symptoms associated with diarrhœa; in another the patient developed exophthalmic goitre.

It should be remembered that occasionally one meets a case presenting the typical clinical picture of the "achlorhydric syndrome" in which a gastric test-meal discloses a hyperacidic condition rather than the anticipated hypo-acidity. Libert mentions the possibility of hyperacidity in this connexion. We have found one in a series of 53 cases examined. The treatment of such a case with hydrochloric acid is contra-indicated, since alkalis usually relieve the condition, and it is, therefore, a sine qua non that the diagnosis of an "achlorhydric syndrome" necessitates a gastric investigation. We have also noted the frequent history of an operative interference for appendicitis or gastric ulcer in cases subsequently shown to have the typical achlorhydric syndrome on presenting themselves with recurrences of the original symptoms. A similar observation has been made by Levine and Ladd in six of 125 cases of pernicious anæmia. The possibility of abnormal radiographic results in gastric achylia should also be borne in mind (Hines).

Table I. summarises the findings in our series of 53 cases in which gastro-intestinal symptoms were the predominant feature.

TABLE I.

	Male.	Female.	Total.
Achylia gastrica	5	20	25
Hypochlorhydria—			
(*a*) Peptic activity negligible	2	6	8
(*b*) Peptic activity normal	5	5	10
Normal hydrochloric acid—			
(*a*) Peptic activity diminished	0	1	1
(*b*) Peptic activity normal	0	8	8
Hyperchlorhydria	0	1	1
	12	41	53

All the cases were examined by means of a fractional test-meal and the titres for free hydrochloric acid, total acidity, total chlorides, and peptic activity were determined for each sample. The 25 cases with achlorhydria also showed either complete or almost complete absence of peptic activity in all samples —i.e., achylia gastrica. This was confirmed in several cases which were re-examined after varying intervals. The remainder of the cases fell into very definite groups, as shown in Table I.; the highest value obtained in the hypochlorhydric group being 16 units (0·058 per cent.) of hydrochloric acid, while the lowest of the maximum titres in the normal group was 28 units (0·102 per cent.). One case showed hyperchlorhydria (over 70 units of free acid).

TREATMENT.

In the treatment of chronic diarrhœa a great variety of drugs have been tried. The gastric secretory deficiency suggests the use of hydrochloric acid, and small doses (♏ v.–xv.) have been tried by many authors, notably Hunter, Kantor and Sagal, Schneyer, and Martinez. The question of an adequate dose is important. It was shown, as long ago as 1908, by Fischer and by Leo that there was a minimum dose of dilute hydrochloric acid (2·75 c.cm. of 10 per cent. acid) that would produce free acid in the gastric contents, while greater doses (13 c.cm.) often failed to produce free acid. Crohn showed that small single doses of hydrochloric acid, U.S.P. dil. (11·5 per cent.), were neutralised when given to achlorhydric patients and that at least 1·6 to 2·6 c.cm. were required to render the gastric contents acid. Similar observations have been made by Vanderhoof, Hurst, Shaw, and by Kearn, Rose, and Austin, who advocate 4·8 c.cm. of the diluted acid.

As will be seen from our results of gastric investigations above, there is usually a deficiency in pepsin in the gastric juices of achlorhydric patients, and it has been observed by Wilkinson and Brockbank that in cases of pernicious anæmia with gastro-intestinal symptoms these latter are relieved by the use of pepsin together with the acid. We have, therefore, been using this mixture containing acid. hydrochlor. dil. (B.P.), ½–1 drachm, and glycerinum pepsini, 1–1½ drachms, well diluted with water three or four times a day with meals. In all cases, the gastric symptoms due to the achlorhydria have been cured as long as the treatment was continued.

RESULTS AND TREATMENT.

The 43 cases in this group with achylia or hypochlorhydria, and the normal case with diminished peptic activity, were given the above treatment.

(1) Twenty-eight have received treatment for periods of six months to two years and show the following results. Seventeen of the 18 cases with achylia were promptly relieved by the treatment; 16 of them are very well and have been free from gastro-intestinal symptoms (although one occasionally passes some mucus); one improved for eight months, when she developed a subacute atrophy of the liver (Susman and Oliver). The other has improved and is better than before treatment. One case discontinued the acid therapy and relapsed, but is now well again after returning to the treatment.

Of the 10 cases of hypo-acidity, seven are quite well; one still passes some mucus, but is quite well otherwise; and one has very occasional attacks of diarrhœa, which is more marked if she discontinues the acid therapy; one is not improved.

The one case with normal acid secretion but reduced peptic activity has been perfectly well since she commenced this treatment.

The remainder of the cases (eight with normal acidities and one with hyperacidity) were not given the pepsin and hydrochloric acid treatment; of these two are better, two are improved but get occasional attacks of diarrhœa; two are still getting colicky pains; one is slightly better; and two are no better.

(2) The remaining 15 cases (seven with achlorhydria and eight with hypo-acidity) have only received treatment for periods of less than three months and the results have therefore not been included in the above figures. All, however, are showing a satisfactory response at the present time.

Sore Tongues.

Group 2.—In the course of our investigation we very early observed that, while most of our cases complained of such gastro-intestinal disturbances as have already been described, a few gave histories of recurrent sore tongues or of ulcers on the lips and gums. This led us to extend the scope of our work, and we have been able to collect a further group of cases in which the prominent feature is a glossitis or stomatitis with or without a concomitant diarrhœa. Often there is only a glossitis with atrophy of the papillæ, but there may be active ulceration of the tongue, buccal mucous membrane, or soft palate. Usually the ulceration is intermittent, but it may be so severe as to make the patient's life almost unbearable; on the other hand, in one instance there had been a persistent ulceration of the mouth for more than ten years, which had at times been associated with a dermatitis herpetiformis. In nearly all these cases there was either a complete achlorhydria or a marked hypochlorhydria, and in many of them the administration of acid improved the condition. Treatment in this group, however, may be unsatisfactory as, owing to the soreness of the mouth, it is difficult to persuade the patient to persist with the medicine in adequate doses. In this group, also, we were able to carry out fractional test-meals on every case—in some cases repeated at varying intervals with similar results.

Here again, as in Group 1, the 25 cases fell naturally into the arbitrary groups of achylia (9), hypochlorhydria (6), normal acidities (7), and hyperacidity (3). Table II. summarises the findings:—

TABLE II.*

	Male.	Female.	Total.
Achylia gastrica	1	8	9
Hypochlorhydria—			
(*a*) Peptic activity negligible	1	4	5
(*b*) Peptic activity normal	0	1	1
Normal—			
(*a*) Peptic activity negligible	0	4	4
(*b*) Peptic activity normal	0	3	3
Hyperacidity	0	3	3
	2	23	25

* Two cases in Group 1 also complained of sore tongues or ulcers in the mouth, &c.: these are not included in this Table.

Nineteen cases in this group were given the pepsin-hydrochloric acid mixtures.

(1) After periods varying from 4 to 18 months the results were as follows: six patients with achylia gastrica have remained quite well on the treatment; of five showing hypochlorhydria, four are also quite well but the fifth discontinued treatment and now complains of a sore tongue with flatulent dyspepsia. Of two cases with normal acidity but diminished peptic activity, one is no better and the other has had considerable relief from the glossitis but the arthritis is unchanged; the three with hyperacidity were not given the acid therapy.

(2) The nine remaining cases have had less than three months' treatment, but three with achylia and one with hypo-acidity are responding favourably.

These results should be contrasted with those obtained by Sellei, who distinguishes cases with burning and smarting tongues without visible lesions from the actual glossitis we are describing here, and found moderate degrees of hyperacidity to be common. He treated such cases with dilute alkaline mouth washes and administered alkaline mixtures, with or without atropine, finding that prolonged treatment was necessary.

Dermatoses.

Group 3.—Five cases recorded above, three in Group 1 and two in Group 2, had also concomitant skin affections; a sixth case complained of urticaria and angioneurotic œdema. Three complained of recurrent gastro-intestinal disturbances with urticaria, whilst two had persistent ulceration of the mouth associated with a recurrent dermatitis herpetiformis in one case and urticaria in the other. Fractional gastric analysis demonstrated an achylia gastrica in four cases, hypo-acidity in one case, and hyperacidity in one case. Four cases of urticaria have had no further attacks after 6 to 18 months and in the case with dermatitis herpetiformis some improvement has resulted, but treatment has not been sufficiently lengthy as yet to estimate the final result. The patient with angioneurotic œdema and urticaria has only recently been put on to this treatment.

This association with a skin affection is of interest, since one of us (see Wilkinson and Brockbank) has observed two cases, one of pernicious anæmia, in which an urticarial rash was produced by the liver diet (both fresh liver and liver extracts) but was prevented by the use of hydrochloric acid; the other was a case of symptomless achlorhydria which developed a rash while on acid therapy but was relieved when the acid was discontinued. The association of achlorhydria with many of the dermatoses is not unknown, for Ryle and Barber showed that in 12 cases of acne rosacea five had achlorhydria and two hypo-acidity, and promising results were obtained with acid therapy. Similar results have been obtained by W. H. Brown, who examined 50 cases of rosacea and 50 other dermatoses. He found seven with achlorhydria and eight with hypochlorhydria in the first group, and six and five respectively in the second group. Rulison, in a further group of 50 cases of rosacea, found a corresponding proportion of achlorhydric cases. He also noted the frequent association of functional abnormalities, such as neurotic tendencies, subnormal weight, poor muscular tone, visceroptosis, but constipation rather than diarrhœa. Stein has referred to similar findings.

Rheumatoid Arthritis.

Group 4.—The occurrence of rheumatoid arthritis in association with gastric anacidity has been noted several times. Faber (1913) found achylia gastrica in 15 out of 65 patients with chronic polyarthritis. Borries showed that 30 per cent. of 94 cases had achylia by the Ewald one-hour test-meal, whilst Woodwark and Wallis obtained similar results in 10 cases. Coates and Gordon, also using the Ewald test breakfast, obtained achlorhydria in 14 out of 20 cases of rheumatoid arthritis. Using the fractional method of gastric analysis, Bell found three cases of achlorhydria and one of hypochlorhydria in eight cases, but this was not confirmed by Douthwaite and others. Miller and Smith, from a study of 250 cases, came to the conclusion that achlorhydria and hypochlorhydria in chronic arthritis is five times as great as in normal subjects, but only slightly greater than in other diseases. In 420 collected cases of hypo-acidity, Sager and Hartman only found eight cases of arthritis, but this is a misleading figure since there were probably many cases not investigated for gastric acidity. On the other hand, Lottrup recently described a series of cases of chronic progressive primary polyarthritis in which 44 per cent. had achylia gastrica while 58 per cent. had a simple anæmia; this was in contradistinction to other forms of arthritis in which the figures were 15 per cent. and 34 per cent. respectively.

Five of our cases (not included in Groups 1 and 2) of rheumatoid arthritis were examined by us on account of a recurrent diarrhœa (one case) or of a sore tongue (four cases), and six had no other symptoms but the joint affections. These showed achylia gastrica in four cases, hypo-acidity in five, and normal acidities in the remaining two. In all there was a marked improvement in the general health after acid therapy. The sore tongues and chronic diarrhœa were cured, although the arthritic conditions showed some relief in two cases. One patient has since ceased to take the acid mixture and now complains of a sore, dry tongue.

Debility.

Group 5.—Owing to the frequency with which debility and a varying degree of a secondary type of anæmia occurred in these patients, we investigated another series of 10 cases in which debility was the outstanding symptom and in which there were no other physical signs or definite symptoms. In four instances we found an achylia gastrica and in four a hypochlorhydria. In the other two the acidity was normal but there was a reduced peptic activity. Often the history of an indefinite debility extended over a considerable period. In one instance the patient had been operated on 13 years before for a suspected cancer of the stomach and since that time had led the life of a chronic invalid. In nine of these cases the administration of acid was followed by a marked improvement which relapsed if for any reason the acid was discontinued. In one case the improvement was only temporary, but in this instance an intense neurasthenia was the predominant factor. In several of these cases the patient's appearance suggested the presence of a tuberculous focus, but no evidence of this could be obtained either clinically or radiographically. In this connexion, however, it should be remembered that achlorhydria is known to occur in 75 per cent. of cases with advanced phthisis, and the importance of eliminating its presence cannot be too greatly emphasised.

Conclusions.

From our investigations there can be no doubt that diminished or absent secretion of hydrochloric acid is very much more common than is generally supposed, and it may be associated with many conditions which at first sight appear to have little relation to one another. We are not concerned here with such well-known conditions as pernicious anæmia, postero-lateral sclerosis, and late gastric carcinoma.

We have endeavoured to show that in a certain type of case in which gastro-intestinal symptoms are present there is often a marked impairment of gastric secretion, which can frequently be diagnosed clinically and the clinical condition rectified by suitable therapy. It is not clear whether the achlorhydria or hypo-acidity is a primary condition responsible for the symptoms, or whether it is secondary to the gastro-intestinal disturbance. The prompt response to hydrochloric acid therapy would appear to support the former view. On the other hand, the recent work of Farrell, who produced an experimental colitis in animals and showed that it caused a secondary diminution in acid secretion, is in favour of the latter point of view, but the conditions are not comparable.

It appears to be more likely that the deficiency of hydrochloric acid and pepsinogen secretion is a primary condition, and that the absence of the natural antiseptic action of the gastric juice allows an abnormal bacteriological infection to occur in the intestinal tract. As a result, the patient suffers from an intestinal intoxication which may manifest itself in various ways according to the particular individual.

Taking the series as a whole, 76 out of 100 cases show either achylia or hypo-acidity, and a noticeable feature is the predominance of women over men, in the proportion of 55 to 21.

Since cancer of the stomach is very much more common in men than in women, achlorhydria in itself would not appear to be a common factor in its production, as has been suggested by Hurst.

Summary.

A preliminary report is presented in which an association has been shown to exist between a gastric secretory dysfunction and certain clinical conditions (excluding such well-known diseases as pernicious anæmia). A hundred cases have been examined and they fall naturally into five groups.

Group 1.—This group is a definite clinical entity characterised by gastro-intestinal disturbances and recurrent diarrhœa; flatulent dyspepsia and neurasthenia are prominent symptoms. The clinical picture is sufficiently characteristic as to allow the diagnosis of achlorhydria to be made with considerable certainty. There were 53 cases: 25 showed achylia gastrica and 18 hypo-acidity (8 with deficient peptic activity) on examination by fractional test-meal. At periods varying between four months and two years after the institution of treatment with a mixture of pepsin and hydrochloric acid 24 out of 28 are cured, whilst one is very much better, one is better but has occasional attacks of diarrhœa, one is not improved, and one died from subacute liver atrophy. One other case with a normal gastric acidity but diminished peptic activity was also cured by similar treatment. Fifteen cases with achlorhydria or hypo-acidity have been under observation for less than three months but are responding to treatment. Nine others with normal secretion or hyperacidity were not given this treatment.

Group 2.—Comprises 25 cases in which the prominent feature was a sore tongue or an ulcerative stomatitis. The gastro-intestinal disturbances met with in Group 1 may or may not be present. Fractional gastric analysis of these cases showed 9 had achylia, 6 hypochlorhydria (only one having a normal peptic activity), 7 with a normal acidity (four with reduced peptic activity), and 3 with hyperacidity. Treatment was difficult owing to the pain produced by the acid therapy, but ten cases after pepsin and hydrochloric acid therapy had been commenced have not had any further trouble and are now quite well after periods of 4–18 months; one was also quite well until she discontinued the treatment and she now complains of a sore tongue again. Of two with normal acidity, one is much improved and the other has failed to benefit by the treatment. Three with achylia and one with hypochlorhydria out of the nine other cases have responded to treatment, but have not been under observation for more than two to three months.

Group 3.—In five cases skin lesions were complained of in addition to the gastro-intestinal or glossitic symptoms, whilst one other had an urticaria and angioneurotic œdema. Achylia was present in four, hypo-acidity in one, and hyperacidity in one of the cases, and the administration of the pepsin-hydrochloric acid mixture completely relieved the condition in all but the last case.

Group 4.—Five cases of rheumatoid arthritis were examined; one associated with diarrhœa had a hypo-acidity, whilst in four, with histories of glossitis, three had achylia and one hypo-acidity. Six others showed achylia (1), hypo-acidity (3), and normal acidity (2). In all of them the administration of hydrochloric acid greatly improved the general health and apparently alleviated the joint symptoms in two.

Group 5.—Comprises 10 cases of debility with degrees of secondary anæmia, for which no cause could be found. Four had achylia and four had hypochlorhydria. All were very much improved after the administration of hydrochloric acid and pepsin, but one has since relapsed.

In these series the predominance in numbers of women over men is very striking; being 2·6 to 1 in the total number of cases showing deficient gastric secretion but 3·3 to 1 in cases with achylia gastrica.

We wish to thank the honorary physicians of the Manchester Royal Infirmary for kindly permitting us to include some of their cases.

Hospital Accommodation at Swindon.—The Great Western Medical Fund Society has recommended that the G.W.R. be asked to agree to the erection of a new hospital of 80 beds on the present site, the cost, estimated at £44,000, to be lent by the Company on mortgage. Should this course be followed, the suggested amalgamation with the Swindon and North Wilts Victoria Hospital will not take place. The Committee of the Medical Fund Society express the opinion that a voluntary basis and a friendly society basis cannot be satisfactorily amalgamated, and that a hospital run as a joint concern would not give the best results. The recent Swindon hospital carnival produced £2200.

Bucks Small-pox Patients.—The Buckinghamshire county council is desirous of providing a small-pox hospital for the southern part of the county, but the Ministry of Health refused permission for the use of a site at Beaconsfield. The Middlesex county council has now declined to allow of the purchase of the old small-pox hospital at Yeading belonging to the Uxbridge and District Joint Hospital Board on the ground that there is no small-pox hospital in the administrative county, that it is undesirable that there should be any such hospital, and that Yeading Hospital is in a rapidly developing district which will probably, in the near future, be the centre of a thickly populated area of working-class houses.

GRAPHIC BLOOD PRESSURE RECORDS:

A NEW CLINICAL METHOD.

By J. F. Halls Dally, M.D. Camb.,
M.R.C.P. Lond.,

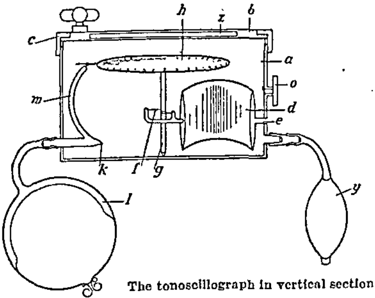
SENIOR PHYSICIAN TO MOUNT VERNON HOSPITAL; DIRECTOR OF THE MARYLEBONE CHILDREN'S RHEUMATISM SUPERVISORY CENTRE.

For many years it has been possible to obtain tracings of blood pressure by means of a kymograph. In clinical medicine, however, through lack of any satisfactory objective mode of registration, a numerical formula has had to represent "the complete arterial pressure picture." [1] A distinct advance has now been made by Prof. J. Plesch,[2] of Berlin, who, after several years' experiment, has succeeded in perfecting the Tonoscillograph, an instrument, which in its final form, ensures graphic and permanent records of arterial and capillary pressures, as well as of individual pulse characters.

The Apparatus.

Fig. 1 is a diagram of the apparatus in vertical section. The outer metal case (*a*) is made air-tight by the hinged lid (*b*), in which is set a glass window, and is fastened by means of the device (*c*). Inside the case (*a*) are two manometer systems. One of the manometers (*d*) communicates through the aperture (*e*) with the outer air, so that the interior of this manometer remains constantly under atmospheric pressure. When the pressure within (*a*) is increased by the rubber inflating bulb (*y*) the manometer (*d*) becomes bent, thus causing the thread (*f*) to be unwound, thereby rotating the table (*h*) fixed to the spindle (*g*). The other manometer (*m*) has a capillary opening (*k*) into the case (*a*), and is in *direct communication* with the armlet (*l*). By pumping air into the case, the armlet simultaneously becomes inflated through the capillary opening (*k*). In this way the thin-walled and highly sensitive manometer tube (*m*) is protected from over-distension. Nevertheless, by means of the capillary opening, equalisation of pressure is secured, so that the external and internal pressures remain the same.

Fig. 1.

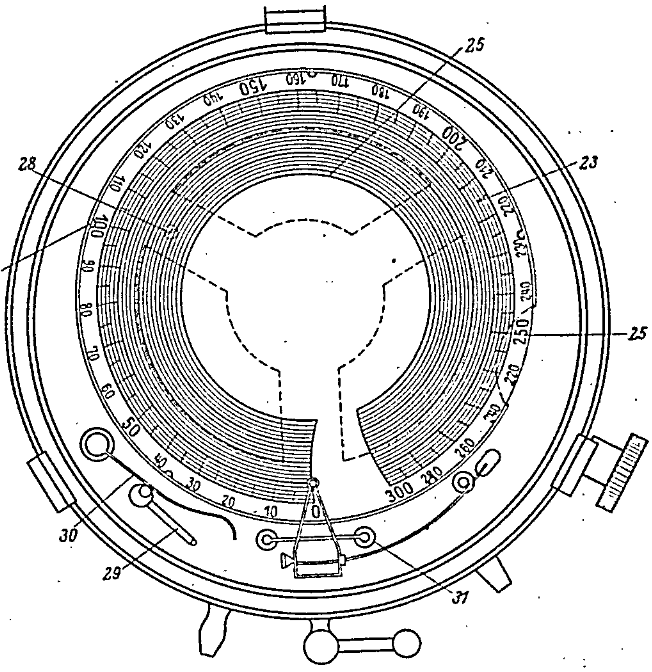


The tonoscillograph in vertical section.

Figs. 1 to 3 by courtesy of Prof. Plesch.

Attached to the manometer tube (*m*) is the writing pen (*n*), which records any movement directly on a graduated paper disc set on the table (*h*). Any increase in pressure caused by the pulse will, therefore, be recorded by this pen before the difference can be equalised through the capillary opening (*k*). The size of this aperture can be regulated by a lever (shown in Fig. 2); it will readily be seen that the stronger the pulse and the smaller the capillary opening the larger will be the oscillations recorded by the pen. Should these oscillations become unduly large in the case of powerfully beating pulses they can be damped by increasing the size of the capillary aperture. The valve (*o*) facilitates even reduction of pressure in order that the disc may return to the zero position. During the time that the pressure is falling the pen (*n*) automatically, and in true accordance with the pulse volume, traces impulses, communicated by means of the armlet, on the disc in the form of a curve, the tonoscillogram.

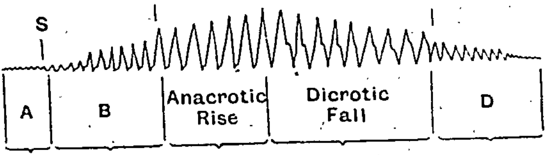
FIG. 2.



The tonoscillograph viewed from above.

Fig. 2 shows the apparatus viewed from above. At the top is the hinge upon which the circular metal lid surrounding the glass window turns in opening and closing. Opposite to this at the foot is the capillary lever mentioned above; to the left of this is a nozzle for the rubber tube connecting with the armlet, to the right an attachment for the inflating bulb; still further to the right a screw-valve for securing even release of internal pressure. The paper disc (25), graduated from 0 to 300 mm. Hg, rests upon a rotating aluminium table (23), the edges of this being represented in the diagram by broken lines. Tiny projections around its circumference hold the paper disc flat. Opposite (0) is the writing pen with angled supports by which it can be raised or lowered on a transverse bridge (31) actuated by the capillary lever. To the left of the bridge is a spring (30) for arresting movements of the table.

FIG. 3.



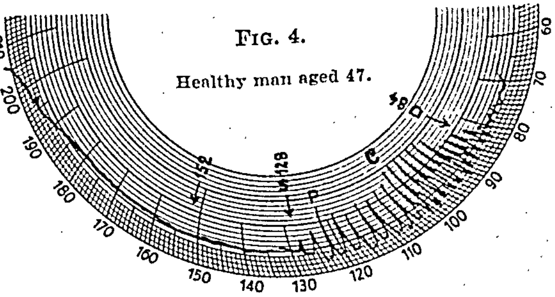
The arterial pressure curve. A, Stages of approach, B, development, C, full oscillations, D, and pulsations respectively; S, systolic pressure; DI, diastolic pressure; P, point at which pulse waves increase to nearly double the height of the preceding waves.

The Records.

Fig. 3 is an analysis of the curve of arterial pressure and volume obtainable with the instrument; the general form of the curve closely resembles those illustrating a paper of mine in 1911 on the sphygmo-oscillometric method of Pachon.[3] As the external pressure is allowed gradually to fall, an approximately even series of small undulations (A) appears as each successive pulse wave impinges against the upper point of arterial constriction. The point for the systolic pressure (S) is marked by the first of a series of slowly increasing waves which, after a varying stage (B) at the point (P) suddenly become almost double the size o the preceding waves From this point u to the largest oscilla tion (C) the increas is much mor gradual. Thenc onwards the curv is flatter in typ the oscillations slow diminishing to th point of diastolic pressure (D), at which they undergo a sudden reduction by half. Throughout the whole of the ascending portion of the curve each oscillation is seen to be separated by a flat interval, which becomes less as the highest oscillation is approached. Thereafter the oscillations assume a peak-like ascent. During the ascending portion of the curve the oscillations are anacrotic in form. During the descending portion they are dicrotic, but only as far as the point of minimal pressure. Beyond this point, the external and internal pressures being equalised, the pulse waves are represented by the stage of pulsations.

FIG. 4.

Healthy man aged 47.



The foregoing stages are exemplified in the following curves of arterial pressure and pulse volume taken from cases under my care (Figs. 4 to 8).

In the case of a healthy man, aged 47 years (Fig. 4) the stage of approach extends from 152 mm. Hg to the poin of systolic pressure (S) at 128 mm. Next comes a shor developmental stage, denoting healthy tone of arteris walls, which ends at 124 mm. (P), from which point the stag of full pulse oscillations with flat anacrotic waves is continued the intervals becoming less spaced and flattened at the bas as they approach (C). Following the ascending portion o the curve ending at (C), *the waves become more uniform in* amplitude (descending portion) with evident dicrotism, this ceasing abruptly at 84 mm., the point of diastolic pressure (D). The stage of pulsations completes the curve-analysis.

Fig. 5 is a case of early but *typical* hyperthyroidism in a lady aged 36, seen in consultation with Dr. R. Tudor Edwards, of Wembley. Herein the various stages of the arterial curve are clearly recognisable.

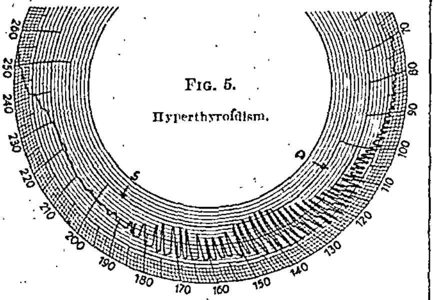


FIG. 5.

Hyperthyroidism.

Fig. 6 is the tracing of a man aged 60 years, 6 feet in height and weighing 15 stone, a teetotaller and non-smoker, athletic in his earlier years and fond of mountain climbing. The chief complaints were of "thumping in the head while in bed," and of pressure feelings referred to the vertex. The heart showed considerable left ventricular preponderance, and a systolic murmur was audible over the whole præcordium with ringing aortic second sound—a case of arterio-sclerosis. (S) is at 194 mm. Anacrotic ascent ends at 150 mm. Descent is gradual to (D) at 104, where dicrotism suddenly ends. Well-marked pulsations follow this point.

In striking contrast to all other curves that I have yet had the opportunity of taking comes Fig. 7, that of a hospital patient, aged 67, housewife, whom I showed in 1925 at the Royal Society of Medicine[4] as a case of hyperpiesia, since established to be of gouty origin.

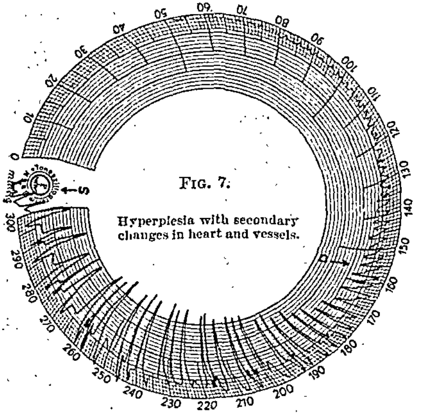

FIG. 7.

Hyperpiesia with secondary changes in heart and vessels.

The present clinical picture is one of cardiac dilatation consequent upon hypertrophy, and changes in the vessels arising independently of renal changes such as occur in the usual forms of Bright's disease. In February, 1930, hæmorrhage occurred in the left retina with impairment of vision two days later. One month after this blurring of speech was noticed, which persists. The arterial curve is of unusually bold character, despite the fact that the capillary lever was turned to the full extent so as to damp the amplitude of oscillations. Each pulse beat is seen to be enormous, corresponding clinically with a pulse of full volume and high tension. At every third beat is a regular sequence of premature contractions. The systolic pressure is at approximately 306 mm., but cannot be precisely fixed because this sphygmomanometer, like the majority of others, has been constructed on the assumption that pressures above 300 mm. Hg cannot occur. This patient's pressure, however, when first seen was 320 mm. systolic, and I have had other cases in my own practice with maximal pressures above 300 mm. The diastolic pressure is reached at 155 mm., giving a differential pressure of about 150 mm.

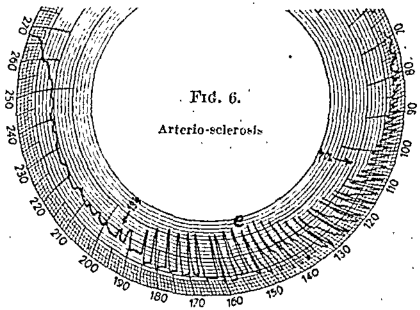

FIG. 6.

Arterio-sclerosis.

Fig. 8 may be regarded as the opposite of Fig. 7 in that it is an example of very low arterial pressure. (S) stands at 94 mm., and (D) at 64, thus yielding a small differential pressure of only 30 mm. The amplitude of oscillation is comparatively tiny, although the capillary lever was set to the smallest opening so as to secure as large excursions of the pen as possible. The picture is one of low vitality and low resistance.

Comparison of tonoscillographic curves brings out many additional points of fresh value and significance. The time factor is as yet far too short for me to enter into any detailed discussion of these. Hence I have put forward merely an outline sketch of the apparatus, and its possibilities in the belief that other workers may be sufficiently interested to profit by the opportunities that Prof. Plesch has so ingeniously afforded.

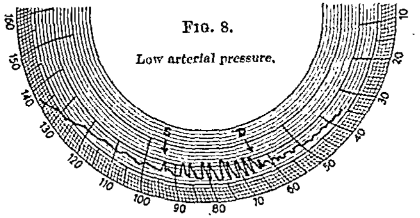

FIG. 8.

Low arterial pressure.

NEMBUTAL AS A BASAL HYPNOTIC IN GENERAL ANÆSTHESIA.

BY I. W. MAGILL, M.B. BELF.,
ANÆSTHETIST TO THE WESTMINSTER HOSPITAL.

THE use of the derivatives of barbituric acid as anæsthetics and hypnotics has been closely studied during the last two years, especially in the United States, and the literature is now extensive. Lundy quotes no fewer than 466 references.[1] As regards the use of the barbiturates in human surgery, one may draw the following conclusions from the latest reports [2]:—

1. The employment of a barbiturate as the sole anæsthetic is inadvisable.
2. As basal hypnotics the barbiturates are among the most valuable drugs available in surgery.
3. The suitability of a barbiturate as a basal hypnotic depends largely upon toxicity and shortness of action. The greater the toxicity the smaller is the dose required, and the smaller the amount of the drug to be detoxicated or eliminated. This results in a shorter period of recovery and lessens the disadvantages associated with prolonged hypnosis such as delirium and depression. The extra nursing care of a patient unconscious for many hours is also obviated.

Nembutal (sodium ethyl methyl butyl barbiturate) has these characteristics more clearly developed than any barbiturate so far discovered. It is about twice as toxic as sodium amytal,[3] and its action is much shorter. Lundy states [3] that it is more sedative than hypnotic and that it causes delirium and restlessness less often than other barbiturates. Nembutal (Abbott) is supplied in capsules (grs. 1½) for oral or rectal administration, and in ampoules (grs. 7½) for intravenous use after being dissolved in distilled water (10 c.cm.).

I have administered nembutal as a basal hypnotic to 262 patients. The intravenous route was used in 180 patients, whose ages varied from 9 to 74 years. Oral or rectal administration was employed in the remaining cases which included young children, the aged, obese subjects in whom the veins were not readily accessible, patients in whom the immediate operative risk was extreme, and some cases in which spinal analgesia followed. The age in these patients was between 3 and 84 years. The operations included laparotomy for various conditions, excision of the rectum, tongue or breast, exophthalmic goitre, tonsillectomy, and various plastic operations. Except in cases in which spinal analgesia was employed, the supplementary anæsthetic was nitrous oxide and oxygen with the addition of ether when necessary.

Administration.—Atropine (grs. 1/100) is given half an hour before operation and in adults morphia (grs. 1/6 to 1/4) in addition, providing no contra-indication exists. When the oral or rectal route is selected, nembutal in capsule is given to adults at the same time as the hypodermic injection. For children, for reasons to be given later, it is more satisfactory to administer grs. 1½ two hours before operation in order to judge the response, and to repeat the dose one hour before operation if the sedative effect obtained is insufficient. For intravenous injection a 10 c.cm. syringe is used with a fine hypodermic needle, and the solution is injected at the rate of about 1 c.cm. per minute.

Effect of the Drug.

1. When given by *mouth* or by *rectum* nembutal has a sedative effect which may amount to mild amnesia or actual sleep. In operations in which complete muscular relaxation is not required, supplementary anæsthesia can be maintained with nitrous oxide and oxygen, without cyanosis. Where complete relaxation is essential, the addition of ether is necessary, but the amount is much reduced. Irrespective of whether ether has been added or not, the sedative effect of nembutal continues for one to five hours after operation according to the reaction of the patient. There is a desire to sleep, and nausea and vomiting are diminished, or more usually absent. The patient can be easily aroused while in this state and may respond to questions, but the memory of events at this period is hazy or absent .

2. When administered *intravenously* the injection need not be begun until ten minutes before the time of operation, for the effect is quickly and accurately obtained. No calculation of dose on a body-weight basis is necessary, the amount being determined by the progressive effect during injection. The solution should be freshly prepared and quite clear. The injection should be carried out, preferably in bed, at the rate of about 1 c.cm. per minute, a close watch being kept upon the patient throughout. The most satisfactory method of judging the dose is to engage the patient in quiet conversation. The response to questions becomes gradually more and more indistinct, and without any period of excitement the patient passes into a quiet sleep. The dose is the minimum amount necessary to produce this effect after slow and careful injection. Intravenously, the minimum dose in this series was grs. 3, and the maximum grs. 7½. When sleep ensues after intravenous injection respiration is quiet, diminished in amplitude, and normal in rate.

It has been stated that a fall in blood pressure takes place during intravenous administration of a barbiturate,[1] but so far as careful digital determination goes, with nembutal the fall is trivial or absent.

During the course of the operation after intravenous injection the amount of the supplementary anæsthetic required is less than with oral or rectal administration. This is clearly the result of the more exact dosag by the intravenous route. In two laparotomi the amount of ether required to obtain complet relaxation was apparently independent of the actio of nembutal. These cases were exceptional whe compared with others.

Again, owing to the more accurate dosage, the pos operative effect following intravenous injection more marked than with oral or rectal administratio Drowsiness or sleep from one to five hours after operation is the usual course, with hazy memory for even during that period. In a few instances the patier was fully conscious on return to bed.

POST-OPERATIVE COMPLICATIONS.

Irrespective of the dose or method of administratio a variable degree of restlessness was noted during th immediate post-operative period in 13 patients. Fiv were children, and their condition was controlled b potassium bromide. Of the eight adults, fiv responded to morphia hypodermically and the remaining three continued to be restless for several hour One patient who required a considerable amount o ether to obtain relaxation for the removal of retrocæcal appendix began to vomit persistentl on the third day after operation. There was muc abdominal pain and some distension which did no abate until the eighth day. On the ninth day thi patient died suddenly, apparently from pulmonar embolus. No post-mortem examination was obtained and it is questionable whether nembutal was in an way responsible for this result. In one femal patient who stated that she bruised very easily a inflammatory reaction followed the escape of a small quantity of the solution into the subcutaneous tissue.

COMPARISON WITH OTHER BARBITURATES.

In order to compare the results obtainable with other barbiturates, sodium amytal was administered intravenously in 23 cases, and pernocton in 15. All these patients were adults.

Induction of pre-operative sleep with sodium amytal compares favourably with nembutal, but the recovery period is much longer. Pernocton has been reckoned equal to nembutal in toxicity,[2] and the recovery period is about equal. This drug has the advantage of being supplied in solution ready for use. In my brief experience with pernocton, induction of sleep is not so pleasant for the patient, or so uneventful as with nembutal. During injection one patient became violently excited, and in two others there was nausea and retching. One of these patients had previously received nembutal without any such effect.

Discussion.

As with other barbiturates the variable reaction of individuals to nembutal renders the dosage by mouth and by rectum difficult to determine beforehand. This is especially noticeable in children. In general, it may be stated that children are more resistant than adults, and in children the variation has little to do with age or development. For example, one well-developed child aged 7 was fast asleep after the administration of grs. 1½, while another child aged 5, and of small physique, was quiescent, but not asleep after grs. 3 had been given. And yet it has been possible to produce definite amnesia in some adults with grs. 3 only.

It is in the intravenous use of nembutal, however, that the greatest advantage lies. By this method it is possible to determine the dose accurately during injection of the drug. Here, again, the reaction of the patient seems to bear little relation to age, body-weight, or habits. For example, a man aged 33, weighing 15 st., and having an alcoholic history, responded perfectly to grs. 6 before appendicectomy. He was easily controlled, and well relaxed with nitrous oxide and oxygen and about 3 drachms of ether, without any suboxygenation. At the same time several women of slender build and temperate habits required as much as grs. 7 to produce the desired effect.

Whatever the dose, patients are unanimous in their appreciation of this method of induction and the general lessened tendency to nausea and vomiting. This has been borne out particularly in many patients who had been previously anæsthetised on several occasions. These include some who have had experience of avertin and paraldehyde. They include, also, five doctors.

Intravenous injection of a drug in connexion with anæsthesia is open to criticism as an unnecessary complication not unattended by danger. If injection is carried out carefully and slowly, with aseptic precautions, it need involve little more risk, and certainly no more discomfort, than a hypodermic injection. From the adult patient's point of view, a prick with a hypodermic needle is usually expected before an operation, and to many it is more acceptable than the retention of a rectal injection of any kind. Intravenous injection of nembutal is available, further, when rectal pre-medication is ruled out by the nature of the operation. It requires a minimum of apparatus and preparation. It is carried out by the anæsthetist himself without the necessity for his attendance a considerable time before the operation. There is, also, no question of a nurse being called upon to share the responsibility of administration.

Many patients dread an anæsthetic more than the operation itself. By intravenous injection of nembutal it is possible to mitigate these circumstances in a large majority of cases. It is perhaps needless to add that a drug of such potency should only be in the hands of experienced persons fully conversant with all the principles of general anæsthesia. Its use is not recommended as a routine, but only in such cases where the necessity is indicated.

Summary.

(1) Intravenous injection of nembutal provides a pleasant method of bridging the gap between consciousness and unconsciousness before general anæsthesia. (2) The amount of anæsthetic subsequently required is diminished. (3) Post-operative nausea and vomiting are diminished or absent. (4) The chief disadvantage is post-operative restlessness in a small percentage of cases (about 10 per cent.).

CLINICAL AND LABORATORY NOTES

A CASE OF TEAKWOOD DERMATITIS.

BY ELIZABETH HUNT, M.D. LIVERP.,

FORMER HONORARY MEDICAL OFFICER, RADIUM INSTITUTE AND CANCER AND SKIN HOSPITAL, LIVERPOOL; HONORARY PHYSICIAN, SKIN DEPARTMENT, SOUTH LONDON HOSPITAL FOR WOMEN.

ALTHOUGH it is known that workers with teak may suffer from irritation of the skin, the actual number of cases reported is small.

A man, aged 30, presented himself at hospital on May 8th, 1930, complaining of an irritating dermatitis of the dorsal surfaces of the hands and forearms, the face and neck, and the genitals. He stated that the condition had begun on April 10th, and had lasted three weeks, when he had returned to work for three days, but had been forced to stop again owing to recurrence.

In May, 1929, he had had a similar attack, which had lasted three weeks and had been succeeded by boils on the trunk and styes on the eyelids. He was employed as a *shipwright*, and on detailed inquiry as to the nature of his work it was learnt that he had been transferred from metal plates to woodwork, and he believed that the eruption occurred on each occasion after handling teak.

On examination an erythemato-vesicular eruption was observed on the dorsal surfaces of both hands and on the forearms. The face and neck were erythematous, with marked œdema round the eyes. He complained of extreme irritation. The skin was not abnormal otherwise, and no pathological condition was found on physical examination.

The eruption responded rapidly to sedative lotions but, as in the previous year, after subsidence of the acute condition a small number of boils developed.

When recovery was complete the patient was taken into hospital for observation, to investigate his sensitiveness to teakwood before returning to work. On June 4th he was given a piece of freshly sawn teak (Rangoon) to hold in his hand for an hour. Six hours later he complained of irritation on the backs of the hands. The following day there was an erythematous eruption on the backs of the hands and on the face, and the eyes became œdematous; this condition gradually increased in severity until the third day after touching the wood, when there was a well-marked erythemato-vesicular eruption on the dorsum of the hands, the lower third of the forearms, and the face and neck, and the irritation was severe. The condition readily responded to treatment with ichthyol in a zinc calamine lotion.

The effect of teak dust and various teak extracts on healthy skins was investigated by Hoffmann,[1] and as a result of his experiments he came to the conclusion that the irritant action of teak was due to the presence of free unsaturated resinic acid, especially in the dust of freshly cut wood. Willmott Evans [2] considered that the aromatic oil in the heart wood was the essential cause. In the case under consideration the wood used for the test, though freshly sawn, had been in the timber yard for some time. The dust was not applied and heart wood was not used. Some other explanation must therefore be sought.

The interesting features of the case are: the marked susceptibility to, and the shortness of the time of contact with, the irritant; the early onset of symptoms of irritation, which were localised at first and then gradually spread to other regions, although the source of irritation had been removed; and the similarity in the train of symptoms on each occasion, and in their duration.

The simplicity of the method used to test the case suggests that similar methods might be employed with advantage in those numerous medico-legal cases which are now arising where claims are made for compensation for dermatitis due to dyes and other causes.

UNDULANT FEVER

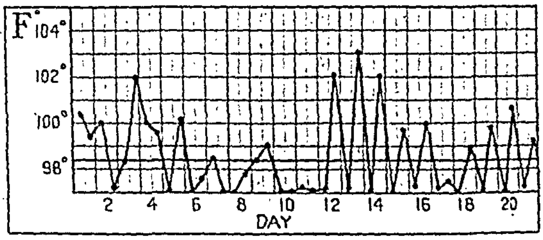
ACQUIRED FROM A GOAT IN ENGLAND.

By Walter Broadbent, M.D. Camb. F.R.C.P. Lond.,

CONSULTING PHYSICIAN TO THE ROYAL ALEXANDRA HOSPITAL; SENIOR PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON.

A boy, aged 3½, was admitted to the Royal Alexandra Hospital on August 8th with a history of having been ill and running a temperature for a month, with no abnormal physical signs until the day before, when he had complained of pain and stiffness in the neck. On admission he lay on his side with his head retracted and his knees drawn up. His head could only be moved slightly without causing pain. There was a blotchy erythematous rash on the body and limbs. He was quite conscious, and his pupils reacted to light. The optics discs were normal. His plantar reflexes were found to be extensor, his knee-jerks were not obtained, and Kernig's sign was doubtful. The diagnosis then made was tuberculous meningitis, and a lumbar puncture was done, but the fluid came out only under slight pressure and no abnormality was found in it. The temperature came down to normal on the 12th and remained so until the 18th, when it went up to 102° F. at night and 103° F. the next night. It had fallen to normal again by August 23rd.

I saw him for the first time on August 24th. He looked to me more septic than tuberculous. His tongue was furred and his breath heavy; acetone had been found in his urine. His bowels were constipated. I could not detect any enlargement of the spleen, nor any abnormal signs. The two waves on his temperature chart made me suggest undulant fever as the diagnosis. A blood count gave a leucocytosis of 16,000, which was against tuberculosis and in favour of undulant fever, though there was no relative increase of lymphocytes, which is said to be usual; polymorphonuclear cells numbered 71 per cent. and lymphocytes 28 per cent. The agglutination test for *Brucella abortus* was negative in all dilutions, but on August 28th the report of the blood culture was—"Growth of very small Gram-negative organisms arranged as paired cocci or short chains of three or four. Short bacillary forms also present. *Brucella melitensis.*" No growth was obtained from the urine.



Temperature chart from August 7th to 27th.

The house physician, Dr. L. P. Clarke, then got into communication with the child's doctor, Dr. Ronald Matthews of Crawley. Dr. Matthews reported that goats had recently come to the farm where the child lived, but that the child had not drunk any goat's milk. However, exactly 14 days after he had first met the milkman who kept the goats, he had developed his first symptoms. The Ministry of Health, on being notified, examined the goats, and found that the blood of one of them agglutinated *Brucella melitensis* in a dilution of 1 in 25. This goat had also aborted twice. This, then, is a case of undulant fever acquired from a goat. Nearly all the cases of undulant fever in England have been due to the *Brucella abortus* of cows.

Sir Weldon Dalrymple-Champney's Report o undulant fever, which can be obtained from tl Ministry of Health, gives a quite complete accou of the various types of the disease and their cause He points out that infection may occur from mill cream, or cheese, but also from dust, or from handlin skins, as the bacilli are excreted in the urine (infected animals for some time. It is evidentl by this latter means that the child was infected, a he did not drink any of the goat's milk. He has no recovered.

I am much indebted to Dr. Lionel P. Clarke for his note and his keen investigations in regard to this case.

TREATMENT OF QUINSY BY LAUGHTER

By C. R. Croft, D.M. Oxf.

The following tale of the late Dr. John Budd i told in Whitfeld's "History of Plymouth an Devonport."[1]

> "An old lady with a tumour in the throat he asked to se him on the following day. She did so, and as she took seat, a dish of boiled dumplings was placed upon the table Without a moment's notice the doctor pelted his assistan with these missiles, the assistant retaliated, and the pa

> cut such sorry figures that the aged sufferer was seized with a fit of uncontrollable laughter and burst the abscess.”

It seems probable that the tumour was a peritonsillar abscess, though admittedly this is uncommon in the aged. The method of treatment is physiological to a degree and deserves further inquiry.

The mechanism is obscure. Sir Arthur Keith gave his opinion that such an abscess would burst under the action of the middle constrictor of the pharynx. I can find no reference in the literature to the movements of the palate during laughter.

A crude examination of the throat in the act of laughing shows two main features, first the descent of the root of the tongue, and secondly the very marked and rapid elevation of the soft palate and the upper part of the faucial arch, presumably by the action of the levator palati. The pillars of the fauces appear to be flaccid and fall together, while the tonsil lying between them does not ascend but rather is held steady by the tongue, or may even descend a little with it. The act of laughter would, therefore, open up the space between the tonsil and the faucial arch, while the suddenness and spontaneity of the action would tear down any adhesions which might be present between these parts.

The following case shows the use of this principle:—

On March 31st, 1930, I saw a married woman, aged 35, with a well-developed attack of acute follicular tonsillitis. On April 3rd swelling and redness above the left tonsil showed that a peritonsillar abscess was impending. On Sunday, April 6th, this was mature, and the patient was suffering very considerable discomfort. The pus seemed to lie deeply, with the origin of the abscess in the posterior part of the supratonsillar recess. I offered her the consolation of the knife but, being a very nervous woman and her relatives away from home, she was averse to the procedure, and I did not press it. Later in the day I returned, prepared at all costs to relieve her discomfort. It transpired that her mother had known Dr. Budd, and it only remained to regale her with the story told above to evoke what laughter her condition would permit.

The effect was dramatic, for, leaning her head over the side of the bed, she evacuated half an ounce of pus into a basin beneath, with immediate relief of her pain and subsequent uninterrupted recovery.

MEDICAL SOCIETIES

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

A MEETING of this Section was held on Nov. 21st, 1930, when Prof. A. H. DAVIDSON gave a presidential address on

Puerperal Sepsis.

Recently work on the bacteriology of the genital tract before and after labour suggested, he said, that the commonest type of severe puerperal sepsis—that due to hæmolytic streptococci—was always an exogenous infection. Non-hæmolytic streptococci were constantly present in the vaginal flora and when resistance was lowered they became virulent and gave rise to an endogenous infection. Predisposing factors played a large part in the causation of sepsis—e.g., lowered resistance due to albuminuria, hæmorrhage, anæmia, or laceration or bruising of the soft parts. Vaginal examination and intra-uterine manipulation must be reduced to a minimum. Many deaths from sepsis followed manual removal of the placenta, an operation which was sometimes rendered necessary by unskilled conduct of the third stage of labour. By way of prophylaxis the patient must be kept in good condition throughout pregnancy and labour. When sepsis had developed, good nursing and the relief of any distressing symptom were of great importance. Drainage of the uterus by postural treatment was essential, and the patient should be made to sit upright in bed for short periods five or six times daily. Intra-uterine douching or exploration should be carried out only when it was reasonably certain that something had been left behind in the uterus. Rheinstätter's curette should never be used in a septic uterus. Hysterectomy and ligation of the pelvic veins had a small place in the treatment of uterine sepsis, but the results were not very encouraging. Many other methods—e.g., glycerin drainage, vaccines and sera, intravenous injection of antiseptics—had had their successes, but none was specific.

Sir WILLIAM SMYLY said that meddlesome midwifery was clearly bad. New methods of interference were frequently introduced, greatly praised, and widely practised for a time, and then fell into disrepute. He thought that at present the chief duty of doctors in connexion with puerperal sepsis was prevention.

Dr. T. M. HEALY thought that nursing did more to help the patient's recovery than any drugs at present known. The chief requirements were sleep and nourishment.

TWO GROUPS.

Dr. GIBBON FITZGIBBON said that cases of puerperal sepsis fell into two distinct groups: (1) those in which the woman after delivery had her tissues undamaged, and (2) those in whom there had been protracted labour, with prolonged devitalising pressure on the soft parts. In group 1 the infection was due to an invasion by pathogenic organisms of a host with a normal resistance. The woman probably had pre-existing susceptibility to infection. In most of these cases the infection was exogenous, due to carriers, indirect contacts, or faulty operative technique, but occasionally the woman was her own carrier—having, for instance, a quiescent dental root infection, or chronic but quiescent infection of the tonsils. The infective organism was always a streptococcus though not necessarily hæmolytic. Such women might have developed general septicæmia after a tooth extraction or an accident. In group 2 the tissues were devitalised by labour. The infecting organism might be exogenous or might belong to the normal flora of the body (staphylococcus, colon bacillus, or non-hæmolytic streptococcus), becoming virulent as a result of tissue damage. In group 1 the course of the disease was like that of any acute infection. The patient might recover in a week or less; she might struggle on and succumb; she might develop enough resistance to localise the disease when recovery would depend on the site of localisation and the possibility of evacuating an abscess; or after weeks of illness she might succumb with partial localisation, or recover without it. The main treatment was general raising of the personal resistance by good nursing, comfort, feeding, and the avoidance of decubitus. When the disease had continued for seven to ten days, localisation must be watched for and treated according to its nature—e.g., multiple abscesses in the uterus requiring hysterectomy, cellulitis, or purulent peritonitis. In group 2 the local condition was important from the outset. The tissue damage might be so great that nothing could be done. The condition was a gangrene; extirpation with a healthy margin might be effective, and was occasionally possible by hysterectomy, but a margin could seldom be obtained, for the parametrium was involved and the result depended upon the patient's resistance holding out until local demarcation had taken place. In this group were infected perineal tears, vaginal tears, and prolonged labours, followed by infection by staphylococci or *B. coli*. Debilitated women who developed thrombosis and phlebitis were usually infected by not very virulent organisms which were localised early or cleared up without localisation, but if the infection was virulent they made little resistance and died rapidly.

Dr. **Bethel Solomons** summarised his opinions as follows: (1) It is wrong to preserve an attitude of watchful expectancy because some treatments do good; at the same time, known harmful treatments should be avoided, and these included intra-uterine douching, digital exploration of the uterus, and curettage. (2) There is a definite but small place for hysterectomy, which if not done too soon or too late will certainly save lives. (3) Glycerin has a *very* small place in treatment; it is especially useful when there is suppression of lochia. (4) To await definite localising signs in every case would retard progress in knowledge. The fact that a patient developed pneumonia, said Dr. Solomons, did not mean that she had not sepsis, for pneumonia was often an end-result of sepsis. This nullified the value of statistics about sepsis, for many cases which were reported as deaths from influenza or pneumonia should rank as septic death. When a patient died of sepsis after Cæsarean section it did not necessarily mean faulty technique; the patient was often profoundly infected at the time of the operation. As regards forceps, it must be admitted that any operation increased the risk of sepsis, but it was often unfortunately necessary to apply forceps to save infant life. The lying-in institution was a safer place than the private house, but the statistics would necessarily always show a higher incidence-rate of sepsis in the former, because of the difficult cases sent in.

MEANS OF IMPROVEMENT.

Dr. D. G. **Madill** said that the report on puerperal sepsis submitted to the last London congress showed 247 cases with 87 deaths—i.e., nearly 33 per cent. Of the 87 deaths, 19 had spontaneous delivery and 68 had active interference. Of the 160 recoveries, 42 had normal labour and 118 active interference. It must be concluded that there were cases of autogenous infection, and this view was supported by the investigations of FitzGibbon and Bigger. In the above series 60 different methods of treatment were used. To prevent sepsis it was necessary to do away with meddlesome midwifery, including unnecessary forceps delivery, and raise the standard of the district nurse by extending her training and by insisting on short post-graduate courses every few years. The one advance in active treatment was the cessation of douching and of the use of the blunt curette. Exploration of the uterus was only permissible if a piece of placenta was known to be retained, or in certain cases to take an intra-uterine culture. When the disease had set in there was no unanimity of opinion on the treatment to be used. It would be useful if the masters and ex-masters of the maternity hospitals would say how they would manage a case (1) in the early stage, or when infection was strongly suspected, and (2) when the disease was established. A great many of the cases listed in the reports of maternity hospitals as normal deliveries did not deserve the term at all, because the women had been in labour for a long time and the tissues were considerably devitalised, and this trauma of the tissues led to sepsis later on. The lines laid down for the treatment of any case of fever seemed to Dr. Madill the best for puerperal sepsis.

Dr. R. J. **Rowlette** said there had been very little advance in the treatment of puerperal sepsis in the last generation or two, whatever advance there might have been in prophylaxis; but he thought that ideas about the causation were now a good deal clearer. The organism most frequently found was the *Streptococcus hæmolyticus*, but there were some cases of acute sepsis due to the *Staphylococcus aureus*. These cases could not be explained as being caused by contamination during the investigation. *S. aureus* was not a common organism in cultures made from the circulating blood. Other organisms were frequently found present in the uterus, such as *Bacillus coli*, but he thought it very doubtful whether *B. coli* was ever the cause of the infection. The suggestion that anaerobes played an important part had never, he thought, been substantiated. One practical advance in the treatment of puerperal sepsis was the abolition of douching. There was evidence also that chemotherapy was injurious. In no condition of bacterial infection was there any reason to suppose that antiseptics introduced into the blood stream had any value. He had often been impressed by the satisfactory results obtained when autogenous vaccines had been given as soon as possible. He had also seen cases in which remarkable results had followed the use of serum, but he thought this could not be depended on, and believed that better results were obtained with vaccines than by serum, while their combined use might also be successful.

Dr. A. P. **Barry** said it was necessary to be certain that a case was really septic, for many cases were treated for sepsis in error.

Dr. G. **Tierney** held that before any advance could be made with vaccines it was necessary to try to estimate the resistance of the patient's blood. At present no such method was available. In acute septic infection the resistance of the patient was so lowered that a vaccine might make the patient worse, and the same was true of sera.

Prof. R. E. **Tottenham** said he always used vaccines in septic cases, and had had very good results. He referred to the danger of imperfect isolation in small private hospitals.

Dr. R. M. **Corbet** pointed out that many treatments hurt the patient very considerably, and the pain lasted for some time. He thought that there was no treatment which was specific, and that any which was not specific, and which caused the patient a good deal of pain, should be discarded.

Dr. A. J. **Horne** maintained that the curtailment of vaginal examinations by students and midwives was very desirable.

Dr. D. J. **Cannon** referred to vaginal discharge in pregnancy.—Dr. **Ninian Falkiner** described a case in which Radiostoleum and S.U.P. were apparently useful and a vaccine after localisation had occurred.

THE ROYAL SOCIETY.

THE CROONIAN LECTURE.

THE Croonian lecture[1] was given on Dec. 11th by Prof. JULES BORDET (Brussels), who was formally welcomed as a foreign member of the Society. He chose as his subject

The Theories of the Bacteriophage.

He began by referring to the striking facts connected with bacteriophagy: that a bacterial culture, grown on the surface of an agar medium, became sprinkled with holes; that a broth to which had been added the active principle was thereby rendered unsuitable as a culture medium; that a turbid microbial suspension, obtained by emulsifying the culture from a solid medium, became clear; and that the active principle regenerated itself in producing its effect. It was, he said, easy to obtain the active principle; it was often found in water, soil, or fæcal materials. Vaccine lymph very often contained a principle acting on the staphylococcus. Gratia, by a whole series of experiments, had proved the absolute identity of the phenomena of Twort and of d'Herelle. It was soon recognised that a number of these principles existed, and that one which acted on a staphylococcus did not necessarily produce any effect on *Bacillus coli*, but sometimes one principle attacked several related species of microbes. When a principle specific for a certain species was brought into contact with another species, its virulence for the latter became enhanced with successive transmissions. The specificity of the principles and their power of adaptation were very variable.

Prof. Bordet outlined the experiments on which d'Herelle had based his virus theory of the bacteriophage: The fact that, in adequate dilution, the spots of lysis on an agar colony were well defined and isolated, was taken by d'Herelle to prove that the virus was present in a corpuscular form and not in a state of solution. In reality, however, the conception of the principle as corpuscular did not strictly involve its being a virus. It lost its activity when heated to about 70°C. It was very probably a colloid, and colloids were, in a sense, composed of particles. Possibly also it might be absorbed by the bacterial debris, and thus be deposited with this debris at certain points on the agar surface. Moreover, even if it were in solution, the phenomenon of isolated spots would still be observed. It was certain that contact with bacteria sensitive to its action was necessary for its reproduction. If gradually diminishing volumes were introduced into a microbial suspension, an extremely weak dose—whether of a virus or of an active principle in solution—would not affect more than a small number of the bacteria present. Individual microbes were not identical, and it was highly probable that they were not all equally sensitive to the lytic principle. When one bacterium succumbed to the principle it became a centre for the regeneration of the agent, which, therefore, became more abundant in the immediate neighbourhood, and could then attack more resistant individuals. Therefore a spot of lysis would appear on each point of the agar on which a more sensitive bacterium had rested. Filtration experiments seemed to show that the molecular or micellar dimensions of the principle were analogous to, if not smaller than, those of the colloidal particles of different albuminoids.

OBJECTIONS TO THE VIRUS THEORY OF D'HERELLE.

The virus theory was seductive by reason of its great simplicity, but the extraordinary resistance of the principle to storage and to the action of chloroform were objections to the presence of a virus. If a very weak dose were introduced into a tube of bouillon inoculated with the sensitive organism, the bacteria would multiply for a few hours, and then the turbid liquid would clarify suddenly; it was difficult to suppose that an intrabacterial virus would attack all the microbes at a given moment almost simultaneously. The facts would be easier to reconcile with the theory of an extrabacterial virus secreting a diffusible ferment, but d'Herelle had shown that the principle could only develop in the presence of living organisms. The regeneration of the principle seemed to be correlated with the bacterial multiplication which preceded the lysis. This seemed favourable to the theory Prof. Bordet had proposed with Cinca ten years before: that the bacterium itself secreted the lytic principle, and that bacteriophagy was in reality an autolysis. With Jaumain he had established that the sensitive bacteria must be not only living but also able to multiply. Lysis and degeneration did not occur in normal saline, but a little peptone or meat extract produced both. The antilytic serum produced in a rabbit retained its activity when heated to 60° C.; a virus that showed such good resistance to storage and chloroform ought not to be destroyed in this way. Stassano and de Beaufort had found that sodium citrate hindered the lytic effect, and Prof. Bordet had shown that the elimination of calcium suppressed the lysis in bouillon and hindered the regeneration of the principle. All the principles required some calcium, but they did not all require the same dose.

BACTERIOPHAGY AND AUTOLYSIS.

The theory of Bordet and Cinca was that the bacteria themselves reproduced the lytic principle. The intense lytic action called bacteriophagy represented the pathological exaggeration of a physiological process. The normal function which in some way acted as the source from which the phenomenon of bacteriophagy originated might have some relation to the phenomena of mutation. Individual microbes of the same species exhibited appreciable differences among themselves. Distinct types became constituted, and an equilibrium might be established between them. The maintenance of this equilibrium could not be easily explained unless there were corrective influences to discipline the evolution of the species by repressing the tendency of certain strains to excessive preponderance. In this regulator-mechanism should be sought the factors determining the appearance of bacteriophagy.

The first difficulty in this conception was the essential transmissibility of the bacteriophage, which was very simply explained on the theory of a filter-passing virus. The theory of autolysis implied that the sensitive bacteria already possessed materials necessary for the formation of the principle before they were brought into contact with it. This idea was quite plausible on a physiological basis; as an analogy might be cited thrombin, which brought about its own reproduction. One of its constituents, serozyme, existed in the plasma in the form of an inactive mother substance, proserozyme. Thrombin had the power of transforming proserozyme into serozyme ready to unite with cytozyme to form thrombin. The process was initiated by contact with some foreign body, but when once a certain amount of thrombin had been formed the contact was no longer essential for the continuation of the process. If it be imagined that the physiological mechanism which presided over mutations was the primary cause of the lytic principle, it was to be presumed that the effects of the principles would bear some relation to the phenomena of mutation, and that the behaviour of different types of bacteria in culture would manifest an antagonism revealed by lytic phenomena analogous to those of bacteriophagy. Prof. Bordet then described experiments which confirmed this presumption. For instance, a bacteriophage very active on *B. coli* would not act in a very weak dose on an enormous quantity of bacilli; it seemed to disappear for a time. It was hard to suppose that a virus would disappear when presented with too great a quantity. In a slightly stronger dose, however, the lytic principle would reproduce itself, but the principle thus formed was modified and was distinguished by the name of "weak principle" in that it only produced a very incomplete lysis. The modification was really qualitative and not quantitative, for even in high concentration the "weak" principle only produced a partial lysis. It could also be produced by allowing ordinary principles in a moderate dose to act for a very short time only on a large inoculation of *B. coli*. In other words, if the experiment were so planned that the principle acted exclusively on the most sensitive microbes, these regenerated a lytic agent which was so exclusively adapted to them that thereafter it would only act on microbes exactly like them. Thus the individuality of a given type of microbe was reflected in the qualities of the principle which it was capable of elaborating.

---

[1] The lecture will be published in full in the next issue of the Proceedings of the Royal Society.

SMOOTH AND ROUGH TYPES AND THE WEAK AND STRONG PRINCIPLES.

An experiment which revealed the connexion between the effects of the principle and the origin of mutations was based on the separation of old cultures of *B. coli* into "smooth" types and "rough" types. The types could be isolated pure, but the smooth tended to give rise to the rough again, especially in bouillon; and the rough, though more stable, could, in time, produce individuals of the smooth type. The weak principle attacked by preference and with great vigour the smooth type, while the rough type presented a pronounced resistance. If a tube of bouillon were inoculated with a drop of the weak principle and a drop of the culture of the smooth type, the liquid remained clear for some hours and then the rough type appeared and multiplied luxuriantly. The smooth culture under the influence of the weak principle underwent a complete metamorphosis into a rough culture absolutely identical with rough cultures produced by separation. In view of these results it was plausible to think that the weak principle might represent a more active form of a substance which the smooth type would normally produce, and which would have the power of making the rough type appear at its expense.

The resistance of the rough type to the weak principle depended very much on concentration. This fact also was unfavourable to the virus theory. After a series of transfers the principle became adapted to the rough strain, and could thereafter be reproduced by making it act on the normal rough type. It had not, however, lost its power of causing lysis of the smooth strain, and, therefore, deserved the name of "strong" principle. Bail and Asheshov had recognised that a single bacteriophagic liquid might contain two principles distinguishable by the size of spots of lysis which they caused on agar. Gratia had identified the principle adapted to the smooth strain ("weak") with the type producing large spots, and the strong principle attacking the rough strain with the type producing small spots. The phenomenon of resistance distinguished the principle, as it was highly specific. The weak principle had no action on the dysentery bacillus, while the strong principle had a powerful action.

If the weak principle could become the strong principle, it was conceivable that the weak principle was itself derived from a principle still weaker, which might be the normal physiological substance responsible for the appearance of the rough at the expense of the smooth strain. If a drop of smooth culture were spread over the whole surface of an agar slope and a small droplet of the weak principle introduced and made to flow down the axis of the surface of the medium, incubation showed a clear stripe of lysis down the middle, bounded by an increasingly thick layer of culture. The layer of microbes contiguous to the clear stripe became slightly transparent, surrounding the stripe with a halo of 2 or 3 mm. thickness. The power of causing a halo seemed to belong only to the weak principle, and the halo was visible because in this region the smooth culture took on the aspect of the rough, as if this metamorphosis were beginning to be accomplished. The weak principle introduced into a suspension of smooth *B. coli*, either living or killed by heat, caused a strong agglutination, but the strong principle did not. It was strange that the weak principle which brought about the metamorphosis from smooth to rough was just the one with the power of agglutinating microbes of the smooth type, even when dead.

In conclusion, Prof. Bordet described experiments indicating that a microbic culture is the seat of perpetual inter-reactions between the individuals which compose it. The appearance of the lytic power seemed to be the index of spontaneous differentiation, but this power contributed to the guidance of evolution in the cultures, since it induced modification in certain receptive types.

PATHOLOGICAL SOCIETY

OF GREAT BRITAIN AND IRELAND.

A MEETING of this Society was held at the London School of Hygiene and Tropical Medicine on Jan. 2nd and 3rd, with Prof. W. W. C. TOPLEY in the chair

A. B. ROSHER (London) had made a systema search for influenza bacilli in the trachea at autc over a period of nearly two years. The proportion of positive results varied from 60 per cent. in the winter to about 15 per cent. in the summer and the curve of frequency corresponded well with the curve of recorded deaths from influenza. Most strain were indol-positive.—S. C. DYKE (Wolverhampton described a case of giant-cell tumour (osteoclastoma originating in the patella, and after six years causing death with widespread metastases in the lungs and elsewhere.—H. L. SHEEHAN (Manchester) had studied the taking up of phenol-red, methylene-blue, and other dyes by the kidney from the blood. Precisely what happens remained undecided, but the resul are difficult to reconcile with the Cushny theory kidney activity.—S. L. BAKER (London) had fou that β radiation of radium killed the virus of th Rous sarcoma and the bacteriophage with more difficulty than ordinary bacteria, but much more easily than it destroyed enzymes and complement.—W. E. GYE (London) confirmed Fujinami's claim that his fowl sarcoma would grow well in ducks.—C. H. ANDREWES (London) showed that the serum of fowls bearing a slow-growing fibro-sarcoma generally *had the power of preventing infection with the* virus of the Rous sarcoma. The sera of some normal fowls did the same.—W. E. GYE and W. J. PURDY (London) by inoculating a goat with filtrates of the Rous sarcoma had obtained a serum which would prevent infection with that tumour and with several other bird tumours. Evidence of the existence of two different antibodies was obtained, only one of which needed complement for its action.—W. SMITH (London) had found that his strain of herpes virus almost constantly produced focal necrosis of the suprarenals in rabbits.—G. H. EAGLES and D. MCCLEAN (London) made out a good case for their having obtained abundant multiplication of vaccine virus outside the body in a medium free from living cells.—W. W. C. TOPLEY, M. GREENWOOD, and J. WILSON (London) *had found that mice on a natural* diet of oats, milk, and water, resisted infection with food-poisoning bacteria better than if they had excess of vitamin A or cabbage, carrots, or mangolds.—H. W. CROWE (London) described some experiments on the bactericidal power of blood.—J. H. DIBLE (Liverpool) showed some curious toxoplasma-like parasites which he had found in the kidneys of mice.—C. H. BROWNING, D. F. CAPPELL, and R. GULBRAUSEN (Glasgow) said that splenectomy made no difference to the occurrence or course of infection of mice by *Trypanosoma congolense*.—L. P. GARROD (London) had found that many organisms of the *group causing thrush gave a common reaction* when examined by precipitin absorption.—A. T. GLENNY and MOLLIE BARR (London) showed the great antigenic superiority of diphtheria toxoid precipitated with potash alum.—R. W. SCARFF (London) had found that splenectomy before the injection of typhoid bacilli much reduced the production of agglutinins, while splenectomy after injection left the animals response unchanged. With injections of foreign red blood corpuscles, preceding splenectomy made no difference to the response, while succeeding removal greatly diminished it.—J. W. BIGGER (Dublin) analysed the influence of various factors on the production of hæmolysin by staphylococci: the most important thing is to keep the reaction neutral or on the acid side.—J. W. BIGGER and W. BOXWELL (Dublin) described a very clear case of auto-hæmagglutination in a patient with a severe anæmia *amenable to liver treatment. It was impossible to* do a blood count or make a proper film except at body temperature.—A. FELIX (London) discussed the O antigen and P. B. WHITE (London) the absorption of agglutinins.—R. A. Q. O'Meara (Dublin) analysed the basis of *the Voges-Proskaner reaction* and demonstrated a new and delicate test for the production of acetoin.—J. D. A. GRAY (Liverpool) showed that the salmonella group of bacilli were especially resistant to the salts of lithium which could usefully be incorporated in media for their discovery and isolation.—W. J. LOGIE (Falkirk) described a case of fatal subpial hæmorrhage caused by a blow which produced no injury to the skull: the perforating arteries were apparently torn through in the cerebral commotion.

DEMONSTRATIONS.

The following demonstrations were also given:—W. G. BARNARD (London): teratoma of ovary with teratomatous metastases in the peritoneum; dermoid cyst of brain; embryonic tumour of kidney; rupture of aorta with dissecting aneurysm; foreign body erosion of aorta.—W. E. GYE and W. J. PURDY (London): series of sporadic fowl tumours.—T. HARE (*London*): *patent ductus arteriosus in an old horse.*—J. A. BRAXTON HICKS (London): ganglionic neuroma; cavernous hæmangeiomata of gracilis and lattisimus dorsi muscles.—J. O. G. LEDINGHAM (London): elementary bodies *in virus diseases; the lining of experimental abscesses* with epithelium.—G. R. CAMERON (London): the intravitam staining of bone with lady's bedstraw and other plants allied to madder.

EDINBURGH OBSTETRICAL SOCIETY.

AT a meeting of this Society on Dec. 19th, 1930, with Dr. H. S. DAVIDSON, the President, in the chair, Dr. JAMES DAVIDSON gave an account of histological changes in

The Liver in Eclampsia.

He had found that the changes in the liver were often much more severe and widespread than is usually recognised. At least three different types of lesion were found—namely, necrosis of the cells of the peripheral zones of the lobules; widespread necrosis of the cells in the central and mid-zones; and in *certain cases no gross hepatic lesions, but only small* areas of focal necrosis. These pathological changes were found (*a*) in cases which clinically were typical of eclampsia, with fits, high blood pressure, &c.; (*b*) in cases with fits and low blood pressure; (*c*) in cases with no fits and high blood pressure; (*d*) in cases with no fits and low blood pressure. In other words, cases diagnosed clinically either as eclampsia or as a severe toxæmia of pregnancy were seen to have the same pathological lesions. Dr. Davidson discussed the striking resemblance of the more severe type of liver lesion to "acute yellow atrophy," and contrasted the renal changes with those found in the liver. *He suggested that the renal lesions were to* a certain extent secondary to the hepatic condition.

Rupture of the Uterus.

Dr. R. EVERETT reported on a case of traumatic rupture of the uterus at the fourth month.

The patient, an unmarried girl of 18, was thrown off the pillion of a motor bicycle going at 30 miles per hour. She was admitted to hospital in a dazed condition, and for several days suffered from cerebral irritation associated with *a moderate degree* of shock and pulse-rate of 120. She had also a Colles's fracture of the left forearm. She gave a history of having missed four periods. There were apparently no abdominal symptoms. She had a slight vaginal discharge from that time for seven weeks when she was readmitted into a gynæcological ward. She was then found to have a hard mass in the right iliac fossa, which was thought to be a hæmatoma of the abdominal wall which had undergone some calcification. On account of the bleeding, curettage was performed, and a few fragments of what appeared to be retained placenta were removed by the curette. The patient was discharged a week later, having had an uninterrupted convalescence with no further bleeding.

Three weeks later she reported at hospital and stated that she was feeling well and had returned to work two days previously. The mass on the right side appeared to be harder, and a radiogram was taken which revealed a lithopædion on the right side. A lipiodol examination was carried out and it was found that the lithopædion was separated from the uterus and was outside the tubes, which suggested that the uterus had ruptured at the right side. At operation the lithopædion was removed with some difficulty; there were numerous adhesions both to it and to the uterus.

The patient was discharged from hospital three weeks after operation, after a satisfactory convalescence, and when she came back, two months later, it was found that her periods were regular while the uterus appeared to be mobile and completely involuted.

REVIEWS AND NOTICES OF BOOKS

Emergency Surgery.

By HAMILTON BAILEY, F.R.C.S., late Surgeon, Dudley Road Hospital, Birmingham; Assistant Surgeon, Liverpool Royal Infirmary; and Surgical Registrar, London Hospital. Vol. I. Abdomen and Pelvis. *Bristol: John Wright and Sons, Ltd.* 1930. Pp. 380. 25*s*.

THIS book is written by a surgeon who has been engaged in emergency surgical work for a number of years. He has kept careful notes of his cases and his opinions have strong claims to consideration. A better name for the book would have been Emergency Operations; for there is no systematic account of the clinical features or diagnostic problems of acute abdominal or pelvic diseases; the information on these subjects is scrappy. But when it comes to operative procedures, Mr. Hamilton Bailey describes clearly and succinctly those methods of treatment which he has found most satisfactory in practice. In general this book forms a reliable guide. There is little to cavil at, and the author merits praise for the high standard which is consistently maintained. Only here and there are his recommendations open to criticism. For instance, in our view stovaine is not the safest nor the best anæsthetic for spinal use (p. 144); the advice to sever the bowel just above a fistula in the upper part of the small intestine and unite it to the transverse colon (p. 275) is not the most satisfactory way to treat this condition; and ileostomy for obstruction, apparently recommended on the authority of Richard Warren (p. 183), is surely open to the objection that the fistula is liable to be made in physiologically obstructed intestine, thus ensuring disaster. The descriptions are mostly so clear and concise that the account of exposure of the kidney on page 277 comes as a disappointment.

We predict that this book will be used widely by that numerous group of surgeons who are called upon only occasionally to deal with surgical emergencies. If they follow the advice offered in these pages with skill their emergency surgery will be of a high standard.

Die Zerebrospinalflüssigkeit.

By Prof. Dr. Med. V. KAFKA. Hamburg: Franz Deuticke. 1930. Pp. 400. M.30.

THE name of Kafka is familiar to English physicians chiefly on account of two reactions with cerebro-spinal fluid, the hæmolysin test of Weil and Kafka, and the paraffin-sol reaction. But his claim as an authority on the cerebro-spinal fluid rests much more on the pioneer work which he published in the years 1910 to 1912 on the presence of ferments in the fluid and the permeability of the choroid plexus in health and disease. We therefore welcome a volume which not only includes the results of this work, and of the abundant later researches which have been founded on it, but brings the whole subject up to date. An unexpectedly large part of the book consists of a discussion of the composition and manner of formation of the cerebro-spinal fluid and its relation to the blood plasma. The part dealing with the changes in disease is relatively small and slight, and technical details receive only passing mention. After a short description of the cells, bacteria, and parasites found in the fluid, a fairly long section is devoted to physical properties such as viscosity, spectroscopy, freezing-point, refraction, pH, and alkali reserve. This is followed by a very full description and discussion of the chemistry of the fluid and of the ferments, hormones, complement, antibodies and other less understood complexes which it may contain. A rather short but interesting chapter on the changes found in various diseases constitutes the second quarter of the book. An account of the changes in the fluid in general paralysis before and after malarial treatment contains much that is unfamiliar in spite of the many papers which have been written on this subject.

The third quarter of the book is a discussion of the formation and absorption of the cerebro-spinal fluid. Here the author is surrounded by a superabundance of documentary evidence, much of which is mutually contradictory, and it is hardly surprising if he sometimes fails to make out a clear case for either side. As regards the mode of formation of the fluid he considers as unproved the dialysation hypothesis of Mestrezat, which has recently been so ably advocated by Walter. The arguments against this hypothesis which he finds most convincing are derived from experiments which indicate that the percentages of such substances as calcium and chloride, which normally differ in blood and cerebro-spinal fluid, become identical when blood is dialysed against fluid. These experiments contradict others by Mestrezat and Fremont Smith, at any rate in so far as they relate to the chlorides, and are so full of possible sources of error that until they are amply corroborated they form an insufficient basis for the rejection of the dialysate theory as a whole. Similarly, while the author rejects the theory of von Monakow, which postulates a circulation of cerebro-spinal fluid through brain tissue, and that of Hassin, who supposes that the function of the choroid plexus is to absorb and not to secrete fluid, he does not give any clear statement of his own views on the circulation and absorption of the fluid. Thus in spite of much critical analysis of various theories the 80 pages devoted to this subject give us little that is new.

The last quarter of the work consists of a bibliography, nearly 100 pages long, which indicates both the author's scholarship and the immensity of the literature dealing with the cerebro-spinal fluid. For clinicians the book may be disappointing, since so much space is taken up with theoretical considerations and the discussion of abstruse points that little is left for practical details, but research workers and those to whom the subject is already familiar will find in it a remarkably complete résumé of what is already known and many suggestions for further investigations.

Introduction to Mental Hygiene.

By ERNEST R. GROVES, Research Professor of Sociology, University of North Carolina; and PHYLLIS BLANCHARD, Psychologist, Philadelphia Child Guidance Clinic. London: Gerald Howe, Ltd. 1930. Pp. 467. 16*s*.

MENTAL hygiene implies reform and education as regards major and minor mental disorder, and difficulties in social or family adjustment, and this book gathers together the many threads by which it makes connexion with practical problems. The mental hygiene movement has grown rapidly in the United States, and, since it involves a radical readjustment of our views and judgments upon motives and conduct, this extensive résumé of its activities makes us wonder what influence it will ultimately have. "This profound task of salvaging human nature" (p. 28) might suggest the crank, but such matters as the mental hygiene of childhood, the school, business and industry, of religion and social work, are kept in close contact with reality and handled objectively. But the suggestions for class-room discussion and for written reports at the end of each chapter are likely to lead to satisfaction with verbal exercises, and it is doubtful how far the inner emotional resistances present in everyone can be removed by the intellectual approach. A brief acknowledgment leaves the reader to think that Freud's chief contribution to mental hygiene was in pointing out the important rôle of the "psychic trauma" in the ætiology of the psychoneuroses, the working out of a technique for the discovery of the trauma, and the re-education of the patient without the use of hypnosis, whilst Prof. Groves invites discussion of the causes of "parent fixation" after a chapter in which no mention is made of the original use and meaning of that conception. Perhaps the authors decided that to discuss unconscious processes would destroy the simplicity of the subject as they present it. So far as the principles of mental hygiene can be elaborated with that limitation they have produced a useful and up-to-date book.

Diseases of Infants and Children.

By F. M. B. ALLEN, M.D., M.R.C.P. Lond., Assistant Physician, Belfast Hospital for Sick Children. London: Baillière, Tindall and Cox. 1930. Pp. 595. 15*s*.

THIS book is intended to provide senior students and practitioners with a practical manual of disease in children. Theoretical considerations are avoided as far as possible, and symptomatology and treatment considered in detail. A praiseworthy feature is the great proportion of space which is devoted to the commoner diseases which are of real importance in practice. In the chapter on infant feeding the author has made simplicity his principal object, and has certainly achieved it, though possibly at the cost of providing a somewhat limited range of method. The descriptions of the symptoms of common diseases are well done, and will impress the student with the importance of clinical observation, while much recent work has been included in the accounts of treatment. A useful appendix contains details of some laboratory tests and therapeutic measures.

The book is a sound guide to the practical side of pædiatrics.

Die Erkrankungen der Leber und Gallenwege.

By Prof. Dr. GEORG LEPEHNE. München: J. F. Lehmanns. 1930. Pp. 163. M.6.

THIS little volume was written for the *Münchener Medizinische Wochenschrift* and is now published for the first time in book form. It is a short and clear account of diseases of the liver and gall-bladder primarily intended for the general practitioner. After an initial account of pathology, diagnosis, and therapy in general, the succeeding nine chapters are devoted to liver disorders and diseases, and the last two only to pathological conditions of the gall-bladder and bile-ducts. This is, however, no unfair division, and the chapters on the whole are well balanced. Prof. Lepehne writes definitely and concisely and states the problems at issue fairly and impartially. Biliary drainage, liver function tests, and cholecystography are carefully described. The chapter on catarrhal jaundice, which the author, in line with most present-day authorities, regards as a mild acute hepatitis and not primarily as a catarrhal obstruction, is interesting, and the reader will find other suggestive and provocative paragraphs in this volume. The author's object was to provide diagnostic help to the clinician at the bedside and in no sense to compile a laboratory or technical handbook. This object has been admirably achieved.

Diet in Disease.

By GEORGE A. HARROP, JR., M.D., Associate Professor of Medicine, Johns Hopkins University. Philadelphia: P. Blakiston's Son and Co., Inc. 1930. Pp. 404.

THIS should prove a useful handbook for those engaged in medical practice. Approximately one-half of the book is occupied by an account of the principles of nutrition and the special properties of common foods, and the remainder is devoted to the dietetic treatment of those diseases and disturbances of nutrition in which regulation of food is commonly acknowledged to play an important part. The subject is treated throughout along thoroughly practical lines, from the point of view of the physician who is anxious to give good advice to the individual patient. The principles determining the construction of suitable diets for such conditions as obesity, undernutrition, anæmia, nephritis, diabetes, and gastro-intestinal disorders are dealt with in turn, and sample diets are given. Among the appendices to the volume will be found food-tables, cooking recipes, and a useful account of the Jewish dietary laws.

Applied Electrocardiography.

By AARON E. PARSONNET, M.D., F.A.C.P., and ALBERT S. HYMAN, A.B., M.D., F.A.C.P. London: Macmillan and Co., Ltd. Pp. 206. 17*s*.

IN the closing paragraph of their introduction, the authors of this book express the hope that it may serve to remove that inferiority complex from which the general practitioner is apt to suffer when he contemplates the use of the electrocardiograph. Whether they have succeeded in that object seems doubtful, but the pages which follow appear to provide more than adequate nourishment for such a complex. In a book intended for students and general practitioners it is quite unnecessary to devote 30 pages to the description of various types of electrocardiographic apparatus. The working mechanism is of no interest to the practitioner; all he wants to know is when and how the instrument will help him in his practice.

In these circumstances dogmatism would be excusable. The subject must be simplified as much as possible. To introduce such generally discarded theories as that of auricular fibrillation being due to causes other than circus movement (p. 106) can only serve to confuse the novice. Again, the interpretation of several of the curves is incorrect. For example, the record on p. 93 is clearly one in which a paroxysm of tachycardia has supervened in a case of bundle branch block, and is not, as is here stated, a case of ventricular tachycardia. Again, the oscillations in Fig. 25 are obviously due to circus movement and not to tremor of the somatic muscles, in which the deflexions are neither so regular nor so slow. The statement on page 6 that the Q.S.U. waves may be relegated to unusual conditions is misleading, while the new terms "incidental" and "fundamental" as applied to extrasystoles scarcely justify their application. The best chapter is that dealing with the electrocardiographic findings in coronary arterial disease; but taken as a whole the book strikes us as hardly suitable either for the beginner or the expert.

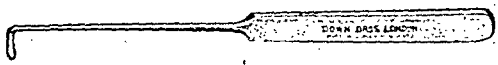
Indian Journal of Medical Research.

THIS issue (Vol. XVIII., No. 2, October, 1930) comprises 366 pages, a special feature being the introduction of a purely clinical paper on Heart Disease in the Punjab by T. A. Hughes and Mohammad Yusuf; 24 out of 35 cases showed valvular disease, 13 being instances of mitral stenosis, which is interesting because rheumatic fever is generally regarded as rare in the tropics.—S. L. Sarkar describes some peculiarities in malaria temperature charts, and concludes that in hyper-endemic areas malaria is more resistant to quinine treatment and more liable to relapse.—C. Strickland and K. L. Chowdhury report on malaria and black-water fever in Naomundi, while T. A. Hughes and D. L. Shrivastava continue their studies on the enlarged malarial spleen.—W. J. Webster also reports further observations on rat fleas and the transmission of plague, and finds that the three Indian rodent xenopsylla readily feed on man in the absence of a more suitable host, even at temperatures of over 80° F. Hot weather was least favourable to *X. braziliensis*, a cold season least suitable to *X. astia*, whilst *X. cheopis* thrived at all periods. In conjunction with G. D. Chitre the conclusion was reached that the chief factor in the spread of plague in Bombay is connected with the blocking phenomenon. The flea species factor is important in so far as a higher *astia* index is required for the progress of plague than will suffice in the case of *cheopis* or *braziliensis*.—A. Vasudevan and N. Seshadrinathan report on some atypical cases of mycetoma, the special features being the peculiar situation and macroscopical appearance of the lesions.—T. A. Hughes and his colleagues record further observations on the serum calcium and plasma cholesterol in health and disease. They confirm their past findings that serum calcium in normal residents of the Punjab is higher than for temperate climates. The blood chemistry of osteomalacia is also considered.—R. McCarrison continues his researches on lymphadenoid goitre in rats, the size of the thyroid gland of albinos being specially considered, while Sankaran reports on the iodine content of the normal thyroid in the latter animals. The effects of high protein diet on this gland are also considered by McCarrison, who finds the high concentration of animal protein in the diet does not cause thyroid enlargement in grown rats, the main factor being deficiency in fat-soluble vitamins.—S. Ranganathan contributes two papers on the composition of urinary calculi, the nuclei of which are shown to be mainly composed of uric acid or urates.—Lucy Wills and M. M. Mehta record the production of pernicious anæmia (bartonella anæmia) in intact albino rats by feeding on diets deficient in vitamins A and C. Their experimental results show that it is possible by diet to produce a severe megalocytic anæmia, especially in female animals. In reality, however, the condition is really a bartonella anæmia occurring in intact animals. *Bartonella muris* was readily demonstrated in the red cells, whilst splenectomy also showed that all their Coonoor stock was infected with it.—P. A. Maplestone has studied the seasonal variation in hookworm in India, and V. T. Korke writes on filaria prophylaxis, the first step being, in his opinion, to keep the cement drains of cesspool systems in strict sanitary order. *Culex fatigans* was found to breed in all systems of drainage under winter and summer conditions.—The number closes with a note by Seymour Sewell on *Cercaria anomala* Rao.

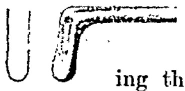
NEW INVENTIONS

A TONSIL-EXPLORING HOOK AND A TONGUE DEPRESSOR.

I HAVE found the instruments herewith illustrated of great use in the investigation and after-treatment of tonsil cases. The *tonsil-exploring hook* is of a convenient size and shape for lifting the anterior faucial pillar off the tonsil, for raising the tonsil from the posterior pillar, for pressing upon the tonsil to squeeze out secretion, and for investigating crypts. The instrument is made in stainless steel. and being somewhat hollowed and rounded, admirably serves its purposes without causing injury.

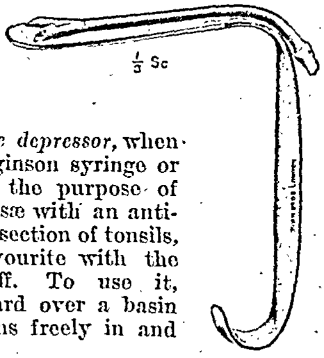


⅓ Sc



FULL SIZE

The *irrigating tongue depressor*, when connected with a Higginson syringe or irrigating can, serves the purpose of douching the tonsil fossæ with an antiseptic solution after dissection of tonsils, and has proved a favourite with the hospital nursing staff. To use it, the patient sits forward over a basin so that the lotion runs freely in and out of the mouth.



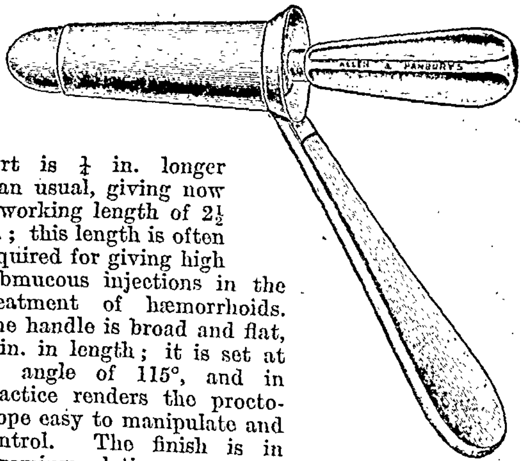
⅓ Sc

The instruments have been made for me by Messrs. Down Bros., St. Thomas's-street, London, S.E.

Clifton. C. OSMOND BODMAN, F.R.C.S.E.

A MODIFIED KELLY PROCTOSCOPE.

THE instrument here illustrated is a modification of the well-known Kelly proctoscope. The tubular part is ½ in. longer than usual, giving now a working length of 2½ in.; this length is often required for giving high submucous injections in the treatment of hæmorrhoids. The handle is broad and flat, 5 in. in length; it is set at an angle of 115°, and in practice renders the proctoscope easy to manipulate and control. The finish is in chromium plating.



The instrument has been made at my suggestion by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W.

W. B. GABRIEL, M.S. Lond., F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, JANUARY 10, 1931.

THE RISKS OF VACCINATION.

THE Committee on Vaccination, appointed jointly in 1926 by the Minister of Health and the Medical Research Council—now known briefly as the Rolleston Committee—has issued a further report,[1] in continuation of Part II. of the report of Feb., 1928, in which the nature and occurrence of acute disease of the central nervous system after vaccination was studied. This earlier report[2] made a series of ten recommendations of which the first four on the technique of vaccination were implemented by the Vaccination Order of 1929 and came into force in October of that year. Since that time a trial has been made of vaccination in *one insertion with a minimum of trauma,* in place of the previously advocated four insertions, and it is rather striking that among the 90 cases of nervous disease set out in the present report, only two are known to have been vaccinated by the one-insertion method. Steps are also being taken, we understand, to comply with recommendation (7) suggesting a revision of the syllabus of instruction of medical students in the light of present-day knowledge of vaccination. The next recommendation was to inquire if it might be possible to increase the dilution of vaccine lymph without impairing its efficacy, and evidence is submitted that a skilled vaccinator using lymph diluted to one in a hundred may be successful in every case, the local reaction being much the same as with a one in five dilution, but with less indication of systemic reaction. The bulk of the report is occupied with an account of the 90 cases of post-vaccinal nervous disease brought to notice since the earlier report, the available clinical information being correlated with post-mortem findings in the 25 fatal authenticated cases. In an appendix is a translation of Sir GEORGE BUCHANAN's valuable report to the Office International which gives the experience of the Netherlands and England up to May of last year. A summary of this appendix appears on p. 97 of our present issue. From this it appears that in the recent large-scale attempt to protect the population of Holland from imported variola encephalitis appeared in the proportion of one in 3437 *children vaccinated between 1 and 2 years,* and one in 815 vaccinated from 6 to 11 years. While all this spadework was necessary to make the story complete, it is admitted that its results do not add materially to our knowledge of post-vaccinal nervous disease. One small item of new knowledge is that the symmetry which usually characterises the distribution of the lesions may be *absent, as in one case set out they were limited to one side of the spinal cord. Speaking generally,* the claim that the lesions of post-vaccinal encephalitis are similar to, if not identical with, those of the nervous affections observed after certain other acute infections, notably the exanthems, has received further support, although attempts made at the Lister Institute to obtain some evidence of the presence of a virus transmissible to rabbits and monkeys have not met with success. No condition simulating post-vaccinal nervous disease has so far been produced by inoculation of monkeys with this material either by the intracerebral, intramuscular, or intravenous routes. Nor was it possible to confirm BLAXALL's demonstration (1923) of the presence of vaccinia virus in the brains of these monkeys.

Attention is called to the experience of J. HEKMAN during the vaccination campaign in Holland. Following, although independent of SIR THOMAS HORDER's use of convalescent serum,[3] it occurred to HEKMAN to attempt to reduce the toxic effects of vaccinia in children by giving serum of their recently vaccinated parents. His success induced E. PASCHEN *to organise the collection and preservation* of sera from recently vaccinated young hospital nurses. Whether or not we are able completely to accept the view of GRÜNEBERG and HEKMAN that vaccinia is alone responsible for the encephalitic sequelæ, their results supply a powerful argument for the use of human antivaccinial serum in these cases at the earliest possible moment. It is now just a matter of chance whether this remedy happens to be available, and the Rolleston Committee suggest that the example of Prof. PASCHEN might be followed by the authorities of large residential institutions, particularly those which require recent vaccination as a condition of admission. In default of human serum Prof. LEDINGHAM and Dr. PETRIE have prepared an antivaccinial serum by immunisation of a horse, and this is now available for trial.

Although, as we have said, the report may contain no substantial addition to our knowledge of the pathology of post-vaccinal nervous disease, it should be widely read for the adequate picture which it gives of an acute nervous disease with a *mortality-rate* of nearly 50 per cent. continuing intermittently to appear, now here and now there, with manifest disregard to the incidence of any known factor other than vaccinia. The quality of the lymph does not appear to have been a determining factor, for in the Netherlands epidemic the lymph used had come from Paris, Hamburg, Vienna, Berne, and other European centres, and even from *Japan and the* Dutch East Indies. In our own country the use of every variety of lymph has at one time or another been followed by nervous disease. The disease is associated with characteristic changes in the brain and cord similar to those found in acute nervous conditions following influenza, measles, and variola. Like them it is dependent on a precedent infection, but *differs in that it follows the infection with great* regularity within a definite limit of time. There is nothing in the circumstances of the cases described in the present report which has not its parallel in previous experience. The age-incidence remains as before. Two-thirds of the patients were children of school age; the youngest child, whose death was certified as due to acute anterior poliomyelitis, was aged 1 year and 8 months. No clinical features not previously observed have been met with; but it may not be without significance that in two cases there was congenital absence of a kidney, and a third had chronic ulceration of bladder with degenerative changes in the kidneys.

◆

LOW GASTRIC ACIDITY.

OPINION on the significance of the gastric acidity has shown considerable changes of late years. When fractional test-meals were introduced there was a tendency to attribute most "dyspeptic" symptoms and many disorders of the stomach to alterations in gastric secretion. A reaction then followed in which the importance of muscular tone and peristalsis in the causation of pain, hunger, and other sensations was more clearly appreciated. Even now we are at least partly ignorant of the precise function of the hydrochloric acid of the stomach. It is certainly a valuable bactericide which helps to protect the alimentary tract from swallowed organisms, but its remarkable variations in health and disease suggest that in other ways it may be more intimately concerned with the functions of the body.

In our present issue Dr. J. F. WILKINSON and Dr. T. H. OLIVER call attention to certain clinical conditions associated with an absence or deficiency of hydrochloric acid in the stomach. The constancy of achlorhydria in pernicious anæmia and subacute combined degeneration of the cord has, of course, long been recognised, and it may be an essential factor in their causation. The fact that it does not disappear, although in other respects the pernicious anæmia may be cured and the blood count become normal, suggests that the achlorhydria is at least a primary if not an inherent or constitutional deficiency. That it is actually often a hereditary abnormality is well known and is exemplified by a family described by WILKINSON and OLIVER in which it was present in three generations examined. It is, however, a frequent finding unassociated with anæmia, when it is commonly secondary or acquired as, for example, from chronic gastritis. Over 100 years ago BROUSSAIS, on the strength of his autopsy findings, considered gastritis to be the cause of almost every variety of pathological condition—even measles. Nowadays many authorities believe that gastric ulceration and often gastric carcinoma follow long-standing gastritis, and there may certainly be a low acidity in gastric ulcer patients, which actually increases after treatment and cure of the ulcer. Low or absent acidity is also a common, though by no means constant, finding in carcinoma of the stomach. The causes of gastritis—and thus of many cases of achlorhydria—may be partly exogenous, and KNUD FABER[1] thinks that achylia is always the result of a preceding gastritis. This, he suggests, may often be due to a deep-seated hæmatogenous infection in childhood, when an apparent anacidity is common. Thus it is found especially in such acute infections as influenza, tonsillitis, diphtheria, and the like, and may perhaps persist in later life. The relative frequency of constitutional and acquired achlorhydria is hard to estimate; its significance, therefore, as evidence of gastritis, is even more so. In either case the part it may play in the causation of symptoms and disease cannot easily be determined. In some cases achlorhydria is associated with diarrhœa, and in this type the condition is often familial. Such lienteric diarrhœa has long been noticed and is discussed by WILKINSON and OLIVER, who report 53 cases in which it formed part of an "achlorhydric syndrome," usually with accompanying neurosis. Typical lienteric diarrhœa, in which the bowels are opened almost immediately after every meal, is probably due to rapid emptying of the stomach and irritation of the gut by food inadequately prepared by the stomach, and similar conditions may certainly follow gastro-enterostomy. But it is by no means common, and the syndrome described by WILKINSON and OLIVER is not so easily recognisable clinically; it may even be found (they admit) with hyperacidity, and a test-meal is therefore essential in the diagnosis. Of 100 cases which they have studied 76 showed achylia or hypo-acidity, and of these 76, 43 had gastro-intestinal symptoms and diarrhœa. Of 100 normal patients (over 60 years of age) studied recently by D. T. DAVIES and T. G. I. JAMES,[2] 44 showed diminished or absent free hydrochloric acid, but gastro-intestinal symptoms were apparently absent. In DAVIES and JAMES's series no case showed an absence of pepsin, whereas a number of WILKINSON and OLIVER's patients showed deficient peptic activity. It is thus obvious that apparent achlorhydria may be commonly present without obvious ill-effects. The exact method used to obtain the gastric juice is clearly of importance, and the use of histamine has shown that many "achlorhydrias" are, in fact, false achlorhydrias in which acid secretion follows its injection. Fear and pain alone may inhibit the acid secretion, and the excess of women over men in WILKINSON and OLIVER's cases suggests that such inhibition may have played some part in the results.

The frequency of gastric anacidity in certain clinical conditions is more than coincidence—e.g., in rheumatoid arthritis, in pulmonary tuberculosis, in acne rosacea and some other skin diseases, in asthma, and in chronic cholecystitis and appendicitis. On the other hand, many such cases show a high degree of acidity, so that achlorhydria can hardly be a direct ætiological factor. As a secondary secretory abnormality its correction might therefore be expected to produce but little benefit. In lienteric diarrhœa the value of hydrochloric acid and pepsin in treatment is undoubted. In other conditions achlorhydria may well be the result of gastritis, and if so it would be rational to treat, if possible, the underlying disorder in the hope of re-educating the stomach to secrete its own acid—as has lately been done by A. F. HURST[3] in a case of pernicious anæmia itself. None the less, nutrition may well be improved by the temporary use of acid in suitable cases, and possibly WILKINSON and OLIVER's unusually successful results are partly attributable to the high dosage they have employed.

◆

THE PSYCHOLOGY OF ACCIDENT NEUROSES.

UNDER the name of *Unfallsneurosen*, or accident neuroses, Dr. MAX EYRICH[4] discusses what we are accustomed to call traumatic neurasthenias. He emphasises the need for separating these psychically determined conditions from organic injuries of the nervous system, the difficulty of the task of distinguishing them being no mark of relationship between the two groups. He notes that the mass problem of the accident neuroses is a post-war phenomenon and, whilst attaching great importance to the influence of compensation, warns against the too easy explanation that the neurotic seizes upon an accident with the simple and conscious aim of obtaining that benefit. He explains that the economic position of the modern worker is insecure, and after an accident it is the threat not of personal injury but of economic disability that brings in its train an anxiety reaction about the future; if this is mishandled at its onset the self-preservation instincts replace ordinary judgments, the road to compensation shows itself, and there begins an interest in the demonstration of occupational unfitness. The need for early recognition and handling of these tendencies is obvious, and Dr. EYRICH believes it is a mistaken view of the situation that deduces a claim to compensation from the presence of nervous symptoms after an accident. The present-day attitude of the medical referee should be changed, for without the prospect of compensation a considerable reduction of these neuroses may be expected.

Anyone familiar with the hopeless wrecks who draw compensation for traumatic neurasthenia years after an accident in which physical injuries were negligible must grant some validity to Dr. EYRICH's arguments and conclusions. These conditions arise when financial responsibility for an accident can be thrown upon someone else; they rarely occur when the victim must bear the brunt of it himself, and it is an old observation that traumatic neurasthenia never follows accidents in the hunting field. If compensation for these disorders could be stopped once and for all, then a great deal of mental deterioration with its associated suffering would be prevented. Probably, on balance, more benefit than injustice would result, but the situation is too complicated for such a simple remedy to be applicable, some of its complications being an inheritance from the days before mechanistic views had been modified by a knowledge of psychopathology. In our last issue, in the first of a series of lectures on that subject, Dr. E. G. HOWE showed the necessity of clearing away misleading labels, of which there is none more misleading than "traumatic neurasthenia." The conception involved is of an actual injury to the nervous system, and in this the patient and his friends firmly believe, effective treatment thus being made almost impossible. Worse than this, the conception is so widely held that he would be a brave witness who faced a jury and propounded the opinions enunciated by Dr. EYRICH, even though they might be in the best interest of the patient, who is usually quite honest in his declaration that he would prefer health to compensation. Another element in the situation is the common failure to diagnose the condition before it is well established, and for this we must blame the neglect of the subject in our curriculum.

Dr. EYRICH is partly right in his statement that the nature of the bodily or mental symptoms is immaterial to the general principle. Accident neuroses differ in no way from the minor psychoses that occur apart from accidents, except in the influence of compensation. They are rarely seen by the psychopathologist, but are sometimes found to be exacerbations of previously existing conditions or developments of an unchecked hysterical symptom that has passed into a state of severe anxiety. All types of people suffer from them, and the over-sensitive worrier, crying out for treatment he cannot obtain, is labelled "traumatic neurasthenia" in company with the slacker who is happy in his solution of the problem of how to live without work.

The occupational offer the same difficulties as the accident neuroses. The old conception of the occupational neuroses as an independent symptom bringing "neurasthenia" in its train, is giving way to the belief that the eponymous symptom is an excrescence upon an underlying mental state, its form being determined by the occupation. The disabling symptoms of miners' nystagmus, whatever may be the cause of the oscillation of the eyeballs, are predominantly those of the minor psychoses; compensation, in the absence of recognition of this fact, has been accompanied by a thirty-fold increase in cost in the last 20 years. In Belgium, with disability pay for a limited period, the disability rarely lasts beyond that period; in this country there is no limit to the one or the other and lifelong disability is not unknown. Yet the disability is real, and in a well-established case the irrevocable stoppage of disability pay would leave the patient in a parlous state and with little chance of recovery. The minor psychoses arise with and without compensation, and the present evil is that in the cases here discussed the sufferers receive, and are taught to look for, compensation rather than treatment. Thus the recommendations of Dr. EYRICH are an effort to retrace false steps that have led to disastrous results; yet the remedy is to be found in a fuller understanding of the nature of the conditions, and the handling of each case in the light of that understanding, rather than in a drastic reform that, whilst being the salvation of some people, may be an injustice to others.

ANNOTATIONS

THE NEW YEAR HONOURS.

THE following is a list of the New Year Honours as far as they directly relate to the medical profession, issued after we had gone to press last week. No medical man has been raised to the House of Lords, but Sir John Rose Bradford, the President of the Royal College of Physicians of London, whose claim to distinction for his long and eminent services needs no emphasis, is created a Baronet.

K.C.B. (Military Division).

Lieut.-General Harold Ben Fawcus, C.M.G., D.S.O., K.H.P., Director-General, A.M.S.

C.B. (Military Division).

Major-General Lawrence Humphry, V.H.S., Deputy Director of Medical Services, Western Command, India.

C.H.

Miss Jane Harriet Walker, M.D., founder of the East Anglian Sanatorium, Nayland, and first President of the Medical Women's Federation.

C.I.E.

Lieut.-Colonel Hugh William Acton, I.M.S., Director of the School of Tropical Medicine and Hygiene, Calcutta.

Major Eric Edward Doyle, D.S.O., I.M.S., Inspector-General of Prisons, Bombay.

Lieut.-Colonel Ian MacPherson Macrae, O.B.E., I.M.S., Inspector-General of Prisons, Bihar and Orissa.

Lieut. Colonel Jasper Robert Joly Tyrrell, I.M.S., Chief Medical Officer in Central India.

K.C.V.O.

Ashley Watson Mackintosh, M.D., Honorary Physician to H.M. Household in Scotland; Emeritus Professor of Medicine in the University of Aberdeen.

M.V.O.

Marcus Antonius Johnston De Lavis-Trafford, O.B.E., M.D., Physician-in-Ordinary to the Duke of Connaught.

C.B.E.

Miss Louisa Martindale, M.D., J.P., President of the Medical Women's Federation.

Miss Agnes Catherine Scott, M.B., Chief Medical Officer and Secretary, Dufferin Funds.

Major Ernest Blechynden Waggett, D.S.O., M.B., Honorary Consultant in diseases of the throat, nose, and ear, Queen Alexandra Military Hospital.

O.B.E. (Civil Division).

Captain Hadji Dabiruddin Ahmad, I.A.R.O., Bengal Medical Service, Teacher of Anatomy, Campbell Medical School, Bengal.

Francis Edward Forward, F.R.C.S., Class I. Prison Medical Officer, Home Office.

Lieut.-Colonel John William McCoy, I.M.S. (retd.), Civil Surgeon and Superintendent of Jail, Sylhet, Assam.

Arthur Hutton McShine, M.D., nominated unofficial member of the Legislative Council of Trinidad and Tobago.

John Richard Cook Stephens, W.A.M.S., Medical Officer, Nigeria.

O.B.E. (Military Division).

Lieut.-Colonel Samuel George Steele Haughton, I.M.S., Officer Commanding Indian Military Hospital, Kohat, India.

M.B.E.

Homewell Lyngdoh, Assam Medical Service, Civil Surgeon, Nowgong, Assam.

Georges Alves Vincent, M.B., Medical Superintendent, St. Ann's Lunatic Asylum, Trinidad.

Knights Bachelor.

Ernest Gordon Graham-Little, M.D., for 15 years a member of the Senate of the University of London, whose work for the interest of the University is well known, is now the independent M.P. for the constituency.

James Smith Whitaker, M.D., is a senior medical officer of the Ministry of Health, a post to which he was appointed on the introduction of national insurance, having been previously medical secretary of the British Medical Association.

Ambrose Edgar Woodall, F.R.C.S., is the superintendent of the Manor House Hospital, Golders Green, and surgical specialist to the Ministry of Pensions.

Kaisar-i-Hind Medal (First Class).

Miss Mary Ronald Bisset, M.B., in charge of the Zenana Baptist Mission Hospital, Bhiwani, Punjab.

Graham Colville Ramsay, O.B.E., M.D., employed on malarial research work by the Ross Institute, Assam.

The following names will be recognised with pleasure in the list, as their owners in different capacities have worked in relation to medicine in one aspect or another. Sir Ernest Rutherford, who has been made a Peer, is chairman of the Advisory Council of the Committee of the Privy Council for Scientific and Industrial Research, and was recently President of the Royal Society. He is professor of experimental physics in the University of Cambridge, where his studies have revolutionised our conceptions of the universe. Dr. Frank Edward Smith, F.R.S., secretary of the Committee over which Sir Ernest Rutherford presides, has received a K.C.B. Mr. Arthur William Hill, F.R.S., director of the Royal Botanic Gardens, Kew, has been promoted K.C.M.G. The C.B.E. has been conferred upon Prof. Sidney Russ, professor of physics, whose work at the Middlesex Hospital in connexion with radium is familiar to all our readers. The O.B.E. has been conferred upon Mr. C. C. Ellis, Senior General Inspector of the Department of Health for Scotland, Captain W. M. Ablewhite, steward of Bethlem Royal Hospital, Mr. J. L. Worsfold, clerk to the Royal Hospitals of Bridewell and Bethlem, and Mr. P. L. Burnett, a devoted worker for the Seamen's Hospital Society. A similar honour is conferred upon Miss T. M. Morton, the organiser of children's care work under the London County Council, while the M.B.E. is received by Miss H. A. Alsop, lately matron, St. Mary Abbot's Hospital. The open-handed contributor to charity who concealed his identity under the pseudonym of "Audax" comes out into the open as Mr. George Roberts, and has been created a baronet.

THE MECHANISM OF SWALLOWING.

THE anatomist of old taught both the structure and the function of the organs and parts of the human body. When the study of function was taken from him by the physiologist, anatomy tended to become a dead science and physiology to go so far into the details of biochemistry and theory that it lost touch with the simple working of the parts. Between the anatomist and the physiologist the radiologist appears, to offer a living functional anatomy. No better example of his services could be offered than Dr. A. E. Barclay's study[1] of the mechanism of normal swallowing, which completely reverses the text-book accounts. What actually happens after the mouth is closed and the nose shut off by the soft palate is that the larynx is raised—as is well known—but its upper part is obliterated not by the epiglottis, which remains upright against the posterior pharyngeal wall, but by the mucous membrane of the laryngeal pharynx, jammed into place by the back of the tongue, which is "swallowed" as far down as the false vocal cords. The passage of the bolus of food is not a peristalsis or a piston stroke, but a suction. The laryngeal pharynx is pulled up behind the larynx towards the mouth as a tubular receptacle, which Dr. Barclay aptly likens to the open beak of the nestling pushed up out of the nest. The suction necessary to pull the bolus from the tongue into the laryngeal pharynx is obtained by a momentary obliteration of the pharynx. For just about one-twentieth of a second before the food passes over it, the pharynx is turned into a potential space, being pushed against the vertebral column behind it by the upward movement of the larynx and the pressure of the back of the tongue in the upper part of the larynx. After this obliteration a negative pressure is, of course, present, and the food falls down the laryngeal pharynx in the shape of a drop with a rounded lower border and a long drawn-out tail like a comet. As soon as the laryngeal pharynx receives the bolus it drops back into its normal position and so opens up the larynx. The suction effect probably lasts until the food reaches the junction of the upper and middle thirds of the œsophagus. Here suggestions of peristalsis are seen on the screen; here the muscle changes from voluntary to involuntary; here the nerve-supply alters; here the muscularis mucosæ becomes increasingly prominent, and here middle-sized foreign bodies almost always stick. Gravity seems to play no part in the passage of the food, for a man can swallow in any position.

---

[1] Brit. Jour. Radiol., 1930, iii., 534.

These observations raise many questions which Dr. Barclay fully appreciates. Nevertheless, as he says, the radiologist can only record observed facts and leave it to others to complete his story.

MALARIA IN DRUG ADDICTS.

THE therapeutic inoculation of malaria in general paralysis and allied conditions has shown the readiness of the subtertian (or malignant) malaria parasite to multiply in the unprotected human body and produce virulent and rapidly fatal forms of the disease. Sometimes inoculation has been accidental. Thus, C. M. Wenyon[1] relates that a number of men were unwittingly infected during salvarsan injections. Though a sterile needle was used for each man, the tubing and glass window were not disinfected between injections, and infected blood corpuscles were thus inoculated into ten successive men, producing attacks of malignant tertian malaria which were fatal in some of the cases. Major A. G. Biggam,[2] professor of clinical medicine in the Egyptian University, Cairo, finds that similar severe and often fatal infections arise from intravenous administration of heroin by depraved addicts in Egypt. The drug is obtained almost exclusively in the Bulac District of Cairo and is administered by a gang quite without any special medical knowledge. The solution of heroin is made up in bulk and administered by syringing, blood being drawn up into the syringe before making each injection so as to ensure that the needle is in position. No sterilisation of the needle is attempted between the injections. The appearance of the veins is characteristic; in some cases there are scars along the superficial veins of the forearm, with dark pigmentation resulting from repeated punctures. Some cases in hospital give a history of as many as three injections in a day. In no other country, Major Biggam thinks, is heroin taken intravenously by drug addicts, and it is probably the success of intravenous injection of tartar emetic in schistosomiasis that has popularised this method of medication in Egypt. By the time they reach hospital most of the addicts are in a wretched condition, very emaciated and mentally unstable. During April, 1929, some of them showed irregular temperatures, and on further investigation, it was discovered that they had a very heavy infection of crescents, or sometimes rings, of the subtertian parasite, which probably accounted for their dysenteric symptoms. In one case subtertian crescents were demonstrated in scrapings from the sigmoid colon. The patients with subtertian malaria were all inhabitants of Cairo where subtertian malaria as a natural infection is unknown. Two possible explanations of this infection are possible: either the heroin lowered their resistance and so made them more susceptible to the bites of infected mosquitoes, or malaria was transmitted to them during the process of injection. The second explanation is by far the most probable. The syringes seized by the police were examined by Dr. A. L. Urquhart, professor of pathology, but though all were found to contain various amounts of decomposing blood clot, no malaria parasites could be demonstrated in this unpromising material. Major Biggam gives details of ten cases, one of which was fatal.

AN INQUIRY INTO THE CAUSES OF MENTAL DEFICIENCY.

FOR some time the Royal Eastern Counties' Institution for the Mentally Defective, at Colchester, has been desirous of making an inquiry into the causation of mental deficiency. This interest was stimulated, perhaps even initiated, by the generous gift of Lady and Miss Darwin, who founded the Darwin Trust and endowed it with an income of about £275 a year. The possibility of research was ensured when the Medical Research Council agreed to contribute nearly half of the salaries and expenses of a full-time research medical officer and a social investigator. These appointments have now been made and work will begin this month. The officer is Dr. Lionel S. Penrose, lately research student at the Cardiff City Mental Hospital, and the investigator is Miss Newlyn, who has been working for the last six years with the Devonshire Voluntary Association for Mental Welfare. The first piece of research is to be a minute inquiry into the physical and mental characteristics, the home environment, and the family histories of the 1400 patients in the Colchester institution.

HYGIENE IN PRIVATE SCHOOLS.

THE President of the Board of Education recently announced the appointment of a departmental committee to consider the relation of education authorities to schools not in receipt of grants from public funds, and what legislative or other changes are desirable in order to secure for the children attending them an adequate education under suitable conditions. The last three words emphasise the importance of the inquiry from a medical standpoint, and the committee includes the names of two medical men—Dr. O. M. Holden, medical officer of health for Croydon, and Dr. Alfred Salter, M.P. The position as it stands is admittedly unsatisfactory, for there are private schools inefficient on the scholastic side, housed in defective buildings, and devoid of medical supervision. To make matters worse, some of the children attending them have been deemed unfit, by reason of mental or physical defect, to attend ordinary elementary schools, and therefore need special care. In practice, all that the local education authority can do is to prosecute the parents for not giving their children an efficient education—a procedure adopted only in extreme cases or where the premises are utterly unfit. But the term "schools not in receipt of grants from public funds" is so wide as to include our public schools, which have their own zealous medical officers, who have an association where the doctors of great public schools discuss matters of common interest with medical officers of elementary schools. Leaving aside such great institutions, it may be said that private schools in general suffer by comparison with State-aided schools in three ways: (1) the buildings may have sanitary defects, and are subject to no special medical inspection; (2) there is no school medical inspection of the children; (3) there is no scheme of treatment and none of the facilities for dealing with exceptional children that are provided by most public education authorities. Further, the teachers in private schools have rarely had the specialised training, including a knowledge of child psychology and hygiene, which come into the curriculum of the training colleges for teachers in elementary schools. Now the buildings could be subjected to inspection by the officers of the school medical service in coöperation with those of the public health authority. In the better private schools medical inspection is being more and more adopted by individual schemes, and in cases where nothing of the kind is contemplated it might be necessary to insist upon its establishment as an alternative to the work being done by the school medical service of the local authority. In some cases it might be convenient to afford children of private schools the facilities for treatment and special care maintained by the local authority, but for the most part the parents would no doubt prefer to arrange privately for medical and convalescent care. Even so the private schools would remain at a slight disadvantage, but not such as to inflict serious injury on the children. It is a matter of experience that the introduction of the doctor into a school, whether officially or by private arrangement, has a beneficial influence on the mental as well as the physical atmosphere of school life.

THE ANATOMY OF LEONARDO.

Leonardo da Vinci, painter, sculptor, architect, engineer and anatomist, occupies a commanding place in the world's history, but while his pre-eminence is unquestioned in so many directions, his achievements as anatomist have often been the subject of discussion, how far he was wholly original and how far he derived from previous knowledge being matters not easy to settle. The vicissitudes of his vast stores of notebooks and sketches, recording his multifarious studies form an interesting story which Prof. McMurrich[1] has set out now in a fascinating work on the master as an anatomist. A critical estimate of Leonardo's place on the roll of fame is directed towards his position as a pioneer, but a historical background is supplied with learning and discrimination, so that the part played by Leonardo in that period of intellectual awakening which he adorned becomes defined. As all his manuscripts dealing with anatomy are now accessible in facsimile, the personal achievements can be compared with those of his successors. There is no call, it seems, to check Leonardo's work as an anatomist with those who preceded him, for his dependence upon Avicenna and Mondino is unconcealed. But how far certain of those who followed Leonardo, notably the great Vesalius, derived help through access to Leonardo's notes, forgetting to acknowledge the inspiration, may not be wholly settled. On the other hand, certain of the claims made in Leonardo's behalf in respect of priority, or of actual authorship, cannot be substantiated. Prof. McMurrich, while sharing the admiration of the world for Leonardo's genius, is no indiscriminate eulogist; on the contrary, he brings out clearly the inconsistencies and errors which are revealed in his scientific work, and which are explained by the position of knowledge in the fifteenth century, when the new learning was barely emancipating itself from the grip of tradition. After a review of the position of anatomical knowledge during the long and sterile period between Galen and Leonardo, and an inquiry into the possible literary sources of Leonardo's anatomical knowledge, we have a series of chapters in which Leonardo's special researches into the anatomy of the various systems are set out. These chapters are in many instances beautifully illustrated, and especially is that the case in the interesting sections dealing with the heart and blood vessels. The main part of Leonardo's knowledge was derived from the autopsies which he conducted, and the pictures, not only in their charm but in their accuracy, show a wonderful advance on any anatomical drawings that had been made previously. At the same time they illustrate very well the preponderating force of tradition as, side by side with exquisite representations of what he must actually have seen, we have drawings perpetuating old theories, the errors apparently being introduced in support of theories themselves erroneous.

This is a loving study, and it is not surprising to learn that Prof. McMurrich found its production to be a heavy toll for some years upon all the time that he could spare from his duties at the University of Toronto. The volume is produced at the instance of the Carnegie Institution of Washington.

HUMANE SLAUGHTER.

In a recent Chadwick lecture, arranged by th Model Abattoir Society, Sir James Douglas dea with the humanitarian clauses of the model by-law issued, in 1915, largely as a result of the evidenc brought before the Admiralty Committee on human slaughtering of animals shortly before. These by laws, which replaced the revision of 1909 and ar probably not as well known as they should be, ru thus:

> "Every person engaged in a slaughter-house in drivin or bringing any animal to the place of slaughter shall (c avoid, as far as practicable, driving or bringing the anima over any ground which is likely to cause the animal to slip o fall and (*b*) otherwise adopt such methods and precaution as will prevent the infliction upon the animal of unnecessar suffering or pain. A person shall not, in a slaughter-hous (1) slaughter or cause to be slaughtered any animal, or dres or cause to be dressed the carcase of any animal, in th view of another animal.
>
> "An occupier of a slaughter-house shall not cause o allow any blood or other refuse to flow from the slaughter house so as to be within the sight or (so far as it is practicabl to avoid it) within the smell of any animal in the slaughter house and he shall not cause or allow any blood or othe refuse to be deposited in the waiting pens or lairs."

There is also a clause in the Protection of Animals Ac (1911) which runs:

> "Nothing in this section shall render illegal any ac lawfully done under the Cruelty to Animals Act, 1876, o shall apply—
>
> (*a*) to the commission or omission of any act in the cours of the destruction, or the preparation for destruction, o any animal as food for mankind unless such destruction o

---

[1] Leonardo da Vinci, the Anatomist. By J. Playfair McMurrich. London: Baillière, Tindall and Cox. 1930. Pp. 265+xx. Price £1 1*s*.

> such preparation was accompanied by the infliction of unnecessary suffering . . . ."

and when interpreted in relation to its context means that no one must inflict unnecessary suffering on a food animal about to be slaughtered either before or during the act of slaughtering.

The Royal Society for the Prevention of Cruelty to Animals, with the help of their honorary adviser, Mr. R. O. P. Paddison, have been publishing what they regard to be the most humane way of killing. For each type of animal a different method is applicable. For beasts the most humane method is the use of the stunning-pen. In the majority of slaughter-houses the animal is led in on a halter or is drawn in by means of a rope passing through a ring fastened to the wall or a beam of the slaughter-house. This is not the best way; for if the beasts see ahead of them daylight or anything white, such as a whitewashed wall, they will walk quietly along a narrow passage into a pen where they may be stunned by mechanically operated instruments. The stunning-pen is a four-sided structure with high wooden sides too high for the animal to look over and a door which can be closed on the animal; the operator leans over the side of the pen. Directly the animal drops, a lever is pulled and the animal rolls out of the side of the pen, the floor lifting at the side opposite the opening. Once outside, it is bled. No blood, therefore, is present in the pen; the animal neither sees nor smells blood nor does it see any carcasses. Such a pen costs about £75, and it would be desirable to introduce one into the plan of every new slaughter-house to be erected. But existing slaughter-houses could be more cheaply altered to allow of more humane methods of bringing in beasts. The passage should be so wide at its entrance that the animal does not mind going in, and no animal should have to be turned round after reaching the slaughter-house. Flooring is of importance; at present concrete floors with ridges are in use, but these ridges wear down and are not renewed. It is not only the animals which dislike slipping about. Prof. Linton is experimenting with a layer of carborundum, ¼ inch thick, on a concrete basis. Progress, too, has been made in making the throwing of beasts more humane; the Islington Board of Schechita has decided to use the newly perfected form of the Weinberg casting machine at the City of London Slaughter-houses where some 30,000 to 40,000 beasts are slaughtered every year.

To kill pigs humanely a suitable pig-trap should be used. The R.S.P.C.A. recommend the Barrett-Smith or the closely similar Schermer type. In both the pig is walked from its waiting pen up a narrow run into the trap which has sloping sides and a floor made to sink. Thus caught the pig is stunned with a humane killer and bled after rolling out of the uplifted side of the trap. The usual way of steadying the pig by means of a loose rope over the upper jaw while he is shot may involve some dragging about. Better, but not so good as the trap, is for an expert slaughterman to walk into a pen full of pigs and shoot one after another, which he can do without causing them any obvious psychical distress. In the case of sheep we find perhaps the most urgent need for the application of the general aim that the waiting pen should be as close as possible to the spot chosen for slaughtering. Many of the ways of handling sheep are far from humane, but the following is unobjectionable. A sheep is brought in either by leading or lifting and placed gently on a crutch (a kind of cradle); the animal is then held in position by a helper and killed by sticking or by a humane killer. A better plan, which enables the operator to work quite alone, is for the slaughterer to bring in the sheep, to lay it gently on the crutch and to pass a strap over its body, one end being fixed to one side of the crutch and the other end attached to a handle at the opposite side. Calves are usually hoisted by a rope attached to both hind legs, and then slaughtered by sticking through the vessels of the neck and by pithing. A better plan is first to stun the animal with a humane killer and then to hoist and bleed.

MENTAL AFTER-CARE.

TO-DAY there is much talk of mental pre-care and mental after-care but, as Dr. G. W. James reminded the recent conference on mental welfare, this country has had a mental after-care organisation for over 50 years, and a very fine work it has carried on all that time. Without it many discharged patients would have been lost indeed. Dr. James told the story of the carpenter who came home to find that his precious bag of tools, his only hope of livelihood and return to normal work, had been pawned during his absence; and of the young man found wandering in the streets of Cardiff, having no memory of what had happened to him since he started out on an errand in an American city months before. Many patients can be released from mental institutions before they are ready for the stress of home life; for these the Association arranges convalescent care in cottage homes. For others it finds work—often no easy matter, for suspicion of the ex-mental patient dies hard among employers—or clothing, or provides a sympathetic friend whose interest will make bearable an otherwise intolerable or lonely environment. It is distressing to hear that the Association is in sore need of funds to carry on this work. Over 2000 cases were helped last year and the certified administrative expenses were less than 8 per cent. Applications for aid are becoming ever more pressing and more numerous. It is to be hoped that the appeal for funds will meet an immediate and generous response. The secretary is Miss E. D Vickers, Church House, Westminster, S.W. 1.

THE VITAMIN CONTENT OF COD-LIVER OILS.

THE latest publication of the Empire Marketing Board is a report[1] in reply to a recommendation from the Imperial Economic Committee (contained in a report dealing with our fish supply) that the nature of the variations in the vitamin content of cod-liver oils produced by fish from various sources should be the subject of inquiry. The underlying causes of such variations were subjected to research, and the methods of manufacture were studied, as well as the refining of the oil for medicinal purposes. Dr. Drummond Shiels, Chairman of the Research Grants Committee, in a prefatory note says that the research work carried out has demonstrated beyond doubt the unrivalled medicinal value of the oils produced in Scotland and Newfoundland, which view makes good patriotic reading, expressed in a rather unusual place. The conclusions of the report have been published for consideration, and it is unfair to the well-known experts to make their results depend, for public estimate, upon a preface. But the general findings of the investigators support the belief that the vitamin value of the oil yielded by the cod caught in Newfoundland waters is the highest, next in order of merit coming the oils of Icelandic and Scottish origin, those from Norway being the least potent. The colorimetric experiments, however, which support this view are not accepted everywhere. The report deserves careful study; the stages of the investigation are clearly set out, and the reasons for the expressed opinions can be readily grasped, while references are given to discussions upon the relative values of the different oils from which opposing views can be ascertained. The general scheme of the experimental observations undertaken in collecting material for the report is an impartial one and the methods for the assay of vitamin potency were carried out with rigid biological tests. In other sections the technical production of cod-liver oil is set out, the report closing with notes on cod-liver oil for human use and animal food.

THE MEANING OF SACRIFICE.

THE wide spread of identical rites and customs for which no rational explanation can easily be given can be considered as the result of diffusion from some common centre or as separate developments of innate human tendencies. The second view is adopted by psycho-analysts, though disputed by some anthropologists, and Freud himself has accounted for the customs of totemism and taboo as derivatives of the primitive œdipus situation. In a thesis recently published[1] Dr. Money-Kyrle brings together descriptions of various rites of sacrifice as gleaned from classical mythology and accounts of primitive peoples, with a critical examination of previous anthropological theories, which attempted to reconstruct the conscious purpose that might have originally provoked those rites. He then attempts to reconstruct the unconscious purpose, and, granted the psycho-analytical premises that he lays down in the first part of the book, he has succeeded in giving to these strange practices a meaning that forms a consistent general picture. The book does not stand alone but represents a recognised mode of approach to anthropological problems; it can be read, however, as a self-contained unit, since the author makes clear those principles upon which his reconstructions are founded. Frazer's "Golden Bough," upon which he freely draws, will long remain our chief storehouse of knowledge of ancient and primitive rites; the interest originally aroused by Frazer's attempt to deduce from them a history of the human mind should receive a stimulus from this application of new views to an old problem.

SODIUM AMYTAL DURING LABOUR.

THE continuing desire for a safe and easily administered anæsthetic that could be widely used to ensure painless confinements has led to the trial of intravenous sodium amytal for the purpose. The results of 46 administrations are carefully recorded,[2] and one gets a clear impression that the desired anæsthetic is still to seek. Although in no instance was the labour prolonged or the mother's physical condition unfavourably affected, yet 11 patients showed extreme restlessness soon after administration of the drug, and restraint became necessary. One patient became maniacal. In all but six of the patients some inhalation anæsthetic was needed at the time of delivery or towards the end of the second stage. One-third of the babies were somewhat apnœic at birth; their condition was "apparently due to a torpidity of the respiratory centre, induced by the drug, and required stimulation to establish respiration." The conclusion is reached that the intravenous administration of sodium amytal during the latter half of the first stage and during the second stage of normal labour induces satisfactory amnesia in nine out of ten cases.

On p. 74 of our present issue we publish a report on basal hypnosis with nembutal, which is another of the barbiturate derivatives.

DECLINED.

A DAILY paper commented recently upon the fact that Mr. Alasdair Alpin Macgregor had received from Major A. G. Church a refusal to Mr. Macgregor's request for an opportunity to debate in a public hall the terms of a speech made by Major Church in Parliament. The speech in question was made in opposition to Lieut.-Commander Kenworthy's motion for leave to bring in a Bill to prevent the application of public money to vivisection experiments. The gist of Major Church's speech will be found in our columns (1930, ii., 1430), and the House refused leave to bring in the Bill. As Mr. Macgregor, in his invitation to a public debate, described Major Church as having spoken in the House "on behalf of the British Medical Association and its vested interests," being either ignorant of his appointment to the Medical Research Council or believing that the latter body and the B.M.A. were identical, it probably seemed to Major Church that this suggested debate would not take place in the presence of an unbiased audience. Such a conclusion was quite justifiable, and upon it the refusal to talk publicly to Mr. Macgregor followed naturally.

Dr. David Shannon will preside over the eighth British Congress of Obstetrics and Gynæcology, which meets at Glasgow from April 22nd to 24th. The first day's discussion will be devoted to the clinical and pathological features of ovarian tumours (excluding endometriomata). The hon. secretaries are Prof. James Hendry, 7 Clairmont-gardens, Glasgow, C.3, and Dr. John Hewitt, 16, Whitehill-street, Glasgow, E.1.

INDEX TO "THE LANCET," VOL. II., 1930.

THE Index and Title-page to Vol. II., 1930, which was completed with the issue of Dec. 27th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

MANCHESTER VOLUNTARY HOSPITALS' COMMITTEE. The annual report shows that the total ordinary income for last year was £307,703, compared with £288,904 in 1928. The total ordinary expenditure was £323,984, compared with £315,615 in the previous year. The net deficit for the year is £12,430 less than that of 1928. The net increase in ordinary income is £20,799, and the increase in expenditure is £8369. The number of admissions to the hospitals was 730 more than in 1928.

A POST-GRADUATE COURSE.

MOTIVES AND MECHANISMS OF THE MIND.*

II.—DYNAMIC PSYCHOLOGY.

THE CONCEPTION OF "PURPOSE" APPLIED TO PHYSICAL ORGANS IN HEALTH AND DISEASE.

IN the previous lecture a distinction was made between those mental disorders in which the disorder was resultant, and those in which the disorder possessed a "function" or element of purpose. This conception of *purpose* in the ætiology of disorder may be traced both in health and disease in organic medicine, and is not only of importance in psychopathology.

The ordered development and specialisation of function of the physical organs of the body may be considered as being *purposive*—for example, the purpose of the alimentary canal is digestion, assimilation, and elimination; and the purpose of the central nervous system is selection, inhibition, and control. The organisation of the body as a whole depends upon a working in harmony of its various functions, a coördination of the purpose of each unit system into a single team, working in harmony under the control of the central nervous system. The purpose of the whole unified system is to produce greater order, freedom, and power over the external environment in which the system lives.

A further instance of purposive behaviour in organic medicine is found in the behaviour of the organs in states of disordered function—i.e., disease. Let us consider, for example, the changes which take place with the introduction of a foreign body into the tissues, and the development of *inflammation.* The introduction of a septic body into the finger gives rise to the cardinal signs of inflammation—swelling, heat, redness, and pain. From one point of view the signs and symptoms of inflammation are regarded as being something undesirable which requires immediate remedy, but when considered in detail the disorder is seen to consist of a series of related purposive interactions on the part of the tissues involved. The introduction of the foreign body causes a reaction on the part of the tissues, the purpose of which is to expel it. The leucocytosis is a massing of phagocytic cells, the purpose of which is to remove the undesirable foreign body. The heat, pain, redness, and swelling are all consequent upon this purposive activity, the increase in temperature of the part being also probably purposive in assisting the remedial process. It is as if the tissues are prepared for the invader with a fixed type of defensive reaction. It cannot be said that there is any *consciousness* of purpose in this response, but it is very important to realise that *consciousness is not necessary for behaviour to be purposive.*

Another example of purpose in organic medicine is found in vomiting. The symptom, when it occurs, is subjectively very undesirable, and the patient applies for a remedy, not realising that the vomiting is itself a remedy for a previous state of disorder. The purpose of vomiting is, again, the removal of a noxious foreign body, to the stimulus of which the muscular part of the stomach reacts with an expulsive impulse.

Nevertheless, the patient is usually quite right in regarding vomiting as needing a remedy. At this stage it is necessary to recognise that, wonderful as are the purposive defensive mechanisms in the human body, these may, and very frequently do, require medical remedy before the system can return to an ordered state of health. It is very important to recognise, on the one hand, the natural purposive remedial aspect of the human body in a state of disease. It is as important to recognise, on the other hand, that this remedial function may itself call for treatment, it being unable to deal effectively with the disorder without medical aid. This point will be returned to when we consider purposive behaviour on a higher plane than that of organic function.

NON-PURPOSIVE OR "RESULTANT" ORGANIC BEHAVIOUR.

A little consideration will show that by no means all organic behaviour can be regarded as purposive. Take, for example, the familiar symptom of *tremor,* which is one of the commonest signs of a disordered nervous system. This is consequent upon a disordered state having arisen in the nervous unit. The process of inhibition, which normally maintains a controlled and ordered tone throughout the nervous system, is broken down in its higher organisation, due, perhaps, to exhaustion or toxæmia, and the symptom of tremor is *resultant* without being remedial or purposive.

A second example of a resultant, non-purposive symptom is the muscular paralysis found in Bell's palsy, where the seventh nerve has been put out of action from some cause. A ptosis of the eyelid due to conjunctivitis may be considered as purposive, but if it is due to nerve paralysis it is resultant and non-purposive.

Another example of non-purposive behaviour is to be found in the development of neoplastic growths. A neoplasm is an independent extension of cells in a parasitic and independent way, at the expense of the normal function of the invaded organ. It is not purposive, and surgical remedies are usually required to protect the body as a whole from the disordered activities of neoplastic cells.

THE IMPORTANCE OF DISTINGUISHING BETWEEN PURPOSIVE AND NON-PURPOSIVE DISORDERS.

It is not many years since the greater part of medical treatment was directed towards the remedy of symptoms and there is still too often a tendency to resort to symptomatic measures. The universal remedy for a headache is aspirin without reference in most cases to the underlying cause. A patient who suffers from insomnia is given hypnotics, or if it be "*nerves*" he is given either sedatives or tonics. But symptomatic treatment ignores the cause of the disorder, and in many cases must leave it still uncured.

The distinction which has been drawn between purposive and non-purposive or resultant symptoms provides the clue to those cases which may be treated symptomatically and those which require deeper insight into the underlying cause. Disorders which belong to the resultant or non-purposive group may, if necessary, be treated individually and symptomatically. Those which are purposive must be treated by a method which seeks to define and remove the cause.

---

* A course of 12 lectures delivered under the auspices of the Tavistock Clinic, Tavistock-square, by Dr. E. Graham Howe during the autumn session of 1930. Lecture I. appeared last week.

In no field of the physician's responsibility has the use of remedies been more symptomatic than in that of mental disorder. Mental disorder differs from organic in that it is more frequently purposive than resultant. The same rule of treatment applies. In order to get the best result from treatment of mental disorder we must define and remove the cause before we can expect to effect a remedy.

In the previous lecture examples were given of enuresis and insomnia in which the disorder was primarily purposive and which cannot, therefore, be expected to respond to symptomatic treatment.

Intractable Illness.

Every doctor is familiar with the disheartening experience of intractable cases of illness which he feels ought to respond to simple remedies, but which, in fact, seem beyond his power to cure. Such patients usually complain of many symptoms which they describe in fullest detail, even with great satisfaction. If a symptom of headache has been improved, pain in the shoulder has taken its place; if the patient is sleeping better, then he is less able to do his work owing to vague feelings of illness or excessive fatigue. Very often such patients in their anxiety to be cured have gone so far as to write down for the doctor a list of their complaints, and successive visits will find modifications in the list, but additions to the number of complaints rather than any sign of cure. They go from one doctor to another, and sometimes their doctor is not sorry to see them go.

If a patient were getting anything out of his illness, if the illness were *purposive*, the intractability could easily be appreciated.

It is quite obvious on a little consideration that illness does achieve a purpose. We are probably all familiar with the feeling that we should like a few days in bed, with someone to be kind to us and give us special attention. Such a rest from the cares and responsibilities of everyday life would come as a welcome relief, but only for a while to most of us. However, the fact remains that a little illness can be attractive under certain conditions. Illness may be still more useful; in fact, it may become invaluable under certain conditions as the following case will show.

Every child wants to be the centre of attention and to exercise some degree of authority. A child of 3 finds his small world enlarged by the introduction into it of a baby brother and, at a single blow, he finds that he has lost both his position in the centre of the domestic stage and his unique dominance over his parents. No one, after having been number one, likes to be relegated to the position of "also ran." An illness causes the displaced one for the time being to recover his position of authority. He is again the centre of the stage, again the one whose slightest whim is met with pleasure and approval. His illness is useful and if his power of adaptability is lacking, if his will to be really strong is not keen, from this early useful experience may be developed the lifelong tendency to invalidism. His illness will be intractable because it is purposive.

CASE H.—A boy of 17 was working in a machine shop at a task he heartily disliked. His father, who was also the foreman, he disliked as heartily as the job. His best friend caught his finger in some machinery and was away from work for three months with compensation. The boy expressed a wish to be ill in order that he also might be able to stay away from work. He got the worst of an argument at home with his father and went to the pictures, where he saw a film of a popular hero who lost his sight, but was married nevertheless to the most attractive heroine, who mothered him happily for the rest of his life. The following day the boy complained of failing eyesight which rapidly developed until he was almost blind. The patient was referred from the eye hospital as a case of conversion hysteria, which was confirmed by the history and circumstances of his illness. He might have been a case of conversion hysteria. His condition seemed at first to improve under hypnotic suggestion, but after a month's unsuccessful treatment he was referred back to the eye hospital where it was discovered that he had bilateral optic neuritis.

Such are the difficulties of diagnosis. Everything was suggestive of a purposive symptom, but it was in fact not purposive, but resultant.

The shell-shock cases of the war provided many instances of purposive disorder which were, nevertheless, quite distinct from the numerous other cases of malingering, with which they were sometimes confused. The man who could face the fact that he felt afraid was not subject to conversion hysteria. The man who could not face the fact, but who had to adapt himself somehow to a situation in which he felt miserably inadequate, was subject to the possible development of conversion symptoms, the purpose of which was to solve his problem for him in a way which was beyond his control. From these causes were developed the cases of blindness, paralysis, fits, aphasia, and innumerable other symptoms—all of which were effective in removing the sufferer from an intolerable situation.

In the case of the malingerer the problem was a conscious one—consciously attempted, consciously achieved. In the true case of shell-shock the problem was not conscious, but was achieved through the natural unconscious method of conversion hysteria, over which he had no conscious control.

Cases of "traumatic neurasthenia" come frequently into the hands of the general practitioner and are always regarded as a difficult problem. They are frequently complicated by the question of compensation. These, again, provide a simple example of a purposive disorder, in which the illness is being useful. It is only natural if there is any question of compensation that the patient should wish it to be as much as possible. He need not consciously think so, but the amount of compensation is going to depend upon the degree of his disability and the tendency is therefore for his disability to be increased. Such cases tend to clear up with greater facility when the compensation is settled. It is easy to suspect a patient of malingering, of consciously exaggerating his disability, but this is not necessarily the case at all. The mechanism for what is called "conversion hysteria" is there, which makes use of the opportunity provided by the disability, quite independently of consciousness. The strain of work under conditions of economic pressure and the everyday difficulties of life are often sufficient in any case to exaggerate the symptoms of illness as a defence, without any question of compensation.

WHAT DO WE "NEED" FOR ADAPTATION?

If disorder is so often purposive, what purpose is it trying to achieve? In other words, what are the needs which all of us tend to feel as essentially requiring fulfilment? They are essentially three: (1) love—a feeling of priority; (2) protection—a feeling of security; (3) power—a feeling of control. Consideration of all the cases already mentioned will show the degree of satisfaction along these three lines which have been attained through illness. The purpose of the disability has been to achieve what the patient wanted or needed, whether he was conscious of it or not. The illness was a means to an end, and the end was love, protection, power—any or all. *It is therefore not true to say that the patient wants his illness, as such.* He does not want it as an end in itself, but he does want it as *a means to an end.* He wants what he gets out of the illness and not, as a rule, any particular symptom. The patient is quite right in saying that he does not want to be ill, and in repeating that he wants to be cured. Furthermore, the patient does not know what he does want. He is not conscious of his need, but love, protection, and power are goals which human nature is pre-ordained to pursue and find attractive.

The child makes use of the thunderstorm or enuresis as a way to finding love and protection in the mother. In the cases of insomnia mentioned in the previous lecture, the symptom was regarded as intolerable, but the purpose of it was to be found in satisfaction of the need for love, protection, and power.

Conflict.

Why should it be necessary to develop a symptom which is itself undesirable, in order to obtain a goal which is desirable? The answer to this question introduces the conception of *conflict.*

There are sometimes reasons why the goal, besides being desired, should be undesirable because it is feared and in those cases a *wish not to* is opposed to the primary goal-seeking wish. Life possesses a primary polarity between the impulse towards inertia and the impulse towards growth. On the one hand there is a wish to retreat, or at least to maintain the status quo. On the other hand, there is the wish to grow beyond the limits of our present experience towards the attainment of higher things. Here, then, is a possible basis for all conflict. But there are other causes for our frequent experience of a duality of opposing wishes.

The importance, at any given time, of previous experience in evaluating the present circumstances is a matter which will be more fully developed in succeeding lectures, but beneath the surface of the man of any age there is always a foundation of previous experience during his own childhood and the childhood of the race. All our wishes are not socially tolerable, nor even consciously acceptable. Social adaptability is a comparatively late development and is superimposed upon primitive childish egotism. This second aspect of conflict is due to the difference between the past and the present, the old and the new, the primitive and the civilised, the child and the man. The wishes and feelings of the one are not tolerable to the wishes and feelings of the other.

Then there is the conflict between the heart and the head, between "feelings" and "thoughts." There are many things that we feel that we would like to do, that we know we must not do, and our heads are frequently in conflict with our hearts. The most important point to recognise, however, is that our heads are frequently unconscious of the wishes or tendencies of our feelings. The cases which have already been cited were not cases of conscious conflict, but of unconscious conflict. The patients do not know what they feel or what they want, nor even that they are getting what they want. We do not realise the extent to which our behaviour is motivated by unconscious processes. On the physical plane inflammation is a purposive unconscious process; on the emotional plane conversion hysteria is another example of a similar purposive unconscious process.

Conflict therefore may be between unconscious feelings and tendencies and conscious wishes. On the one hand there is "I feel I want"; on the other "I think I ought." That often I am not conscious of what "I feel I want" is due to the fact that so many primitive childish "wishes" are a hereditary pattern independent of individual experience. This point will be developed further in a later lecture.

CONSCIOUS CONFLICTS—SUPPRESSION.

If we were to judge from the report of coroners' inquests we should have to believe that conscious conflict was the cause of mental illness. Cases of suicide are usually related to some immediate problem which is consciously in the patient's mind—i.e., disappointment in love, financial anxiety, worry over illness. It is obvious that any of these factors may impose an additional strain, but they are all external factors operating upon the patient's internal psychological constitution, and it is the internal constitution which determines whether or not illness or suicide or any other pathological behaviour may follow. As an axiom it may be stated that conscious conflict cannot, in itself, *cause* an illness, but it may be sufficient to *precipitate* it.

Overwork is frequently cited as a cause of nervous breakdown. The additional strain imposed by long hours, heavy responsibility, and possible financial disappointment is an added burden, which may result in a nervous breakdown, without being the cause of it. For instance, we may ask *why did the patient overwork?* In many cases it will be found that he was trying to do more than anyone would have expected him to be able to do, that he was more critical of himself than he had any right to be, that he was more intolerant of failure and unduly anxious for complete security. With these factors operating he must inevitably tend to overwork and must also finally be disappointed with his achievement. In other words, overwork often depends not upon the external factor of necessity, but upon the internal constitutional factor which would make a patient overwork anyhow, whether it was necessary or not. In this case it may be said that overwork has precipitated the illness, but that the cause lay within the individual's constitution rather than in external circumstances.

CASE I.—A man came for a consultation complaining that he was worried, depressed, and losing his sleep. On inquiry he was found to possess two wives and two families who were ignorant of each other's existence, and at the same time he was a responsible church-worker. When one considers the difficulty of maintaining his social prestige and his domestic problems in watertight compartments, together with the pressure of economic necessity, there need be no surprise at signs of nervous strain. There must have been a great deal of conscious conflict, but there was probably an internal and unconscious motive which prompted him to organise his life in such a difficult fashion.

Conscious conflict may be dealt with by a process of *suppression.* When I am aware that I want two different things I weigh one against the other, and choose the one and suppress the other. This is a conscious process of selection in which one alternative is suppressed in favour of another, and is not to be confused with *repression* which is an unconscious and automatic process.

UNCONSCIOUS CONFLICT—REPRESSION.

It is very difficult to formulate at this stage any ideas which will define unconscious conflict, but the conception will be developed in later lectures. It will be sufficient for the moment to define unconscious conflict as being derived from a source of unresolved past wishes and needs, primitive and infantile. Unconscious wishes have either never entered consciousness or, originating at an earlier stage of development, are not consciously tolerable when they have been retained until a later one.

Childish wishes are very often not consciously tolerable. For instance, a small girl, aged 3, may say to her mother: "When are you going away so that I can go to bed with Daddy?" It is not long before wishes of this kind are dealt with by *repression*. This is an unconscious automatic process which eliminates the wish from consciousness altogether and cuts it out of the conscious mental field of wish-fulfilment. It is out of sight but it is not out of mind and repressed "unconscious" wishes of this kind are very frequently sources of subsequent symptom formation.

CASE J.—An example of this kind occurred in a patient aged 29, who stated that at the age of 23 she was raped by her father. She was able to give full circumstantial details without exaggeration and in a most impressive way which, had they been given in a court of law, and in the light of his known moral character, might well have secured her father's conviction. She had at this time spent about three years in a mental hospital suffering from a very serious nervous breakdown, attributable, as she said, to the shock. Her first breakdown had in fact dated from the age of 23, and her history showed that she had not been well since that time. After she left the mental institution, improved but uncured, she was seen as an out-patient twice a week at the Tavistock Square Clinic, and it became increasingly plain that if the episode which she said was the cause of her illness had actually occurred, it was in fact no more than a coincidence, because it represented her lifelong ambition, although it had never been fully conscious. She was of a very religious disposition—in fact, over-conscientious—and such an idea was quite intolerable to consciousness. She had been a lifelong enemy of her mother, and her most frequent dreams involved her mother's death. There had been many minor episodes of intimacy in which her father had played an unwise part, unaware of what the consequences were likely to be.

She had many symptoms, but only one will be given as an example of repression *and fulfilment of* the unconscious wish. She said that she wished to count everything in fours. This had originated, as far as she remembered, when at 14 she had tried whilst lying in bed, to fit the tiles of the roof across the road, four at a time, inside the four panes of her bedroom window. This was a period of great emotional strain with regard to her father, and was not in fact the beginning of her tendency to count in fours, as she remembered later that as a very small child she liked her doll to have its eyes half-shut, so as to have two lids and two eyes and so make four. She interpreted this *symptom* entirely of her own accord, saying that she was not at all sure that it was right, but that it had just come to her like that. She said "If I start with the figure 4 I feel that this (A in Diagram I.) is my father, this (B) is my mother, and this (C) is me. What I want to do is to go like this. That is my father (A in Diagram No. II.), that is my mother (B), that is me (C), and then I want to make a perfect square (*dotted line D*)—and this is what I *want*. I feel that this is something to make everything complete—like I wanted a baby when I was a little girl, and I feel that the square is something which is quite right and proper, and nothing wrong with it at all."

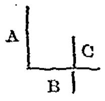

Diagram I.

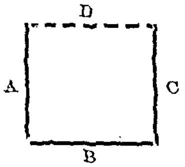

Diagram II.

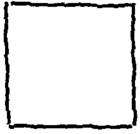
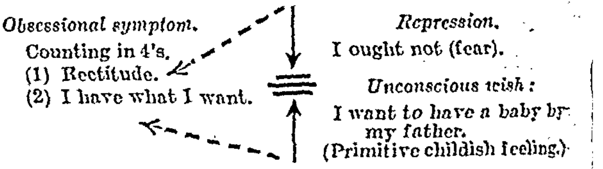
Perfect square



="Rectitude."

In phantasy, the patient had always wanted a baby by her father and she obtained it unconsciously through her obsessional symptom of counting in fours and squares, but she obtained it in such a way as to combine it with a symbol of conscious moral rectitude [illegible]ork.

Solution of Conflict by Symptom Formation.



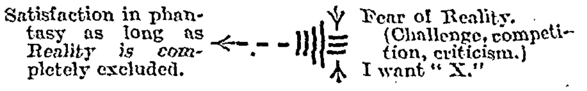
RATIONALISATION.

Rationalisation is the term applied to the satisfactory conscious explanation of wishes and behaviour derived from unconscious sources and unsatisfactory to consciousness. The extent to which this mechanism can take place is almost infinite because of the freedom of the conscious thinking process to arrive at any conclusion which may be satisfactory to itself, which it then embroiders and believes to be true, because it likes it to be so. Most of our thinking suffers from rationalisation—i.e., it is not what is really true, but what we would like to be true. When we are most sure, we usually have least grounds for our assurance, but most wish to be sure. Rationalisation therefore is a process of conscious elaboration and wish-fulfilment. It enables us to prove what we wish to prove and explain in the way that we like, what we should be afraid to explain in a way that is true.

In the case cited above, the patient's consciousness had rationalised her own self-deception by saying that her father had raped her, and that that was the cause of her breakdown. It was only after several months of treatment that she came in a great state of emotional disorder to say: "Doctor, it is not true—*he didn't do it.*" Her unconscious wish had entered consciousness and from that time it lost its power to control her.

PHANTASY.

Solution of Conflict by Phantasy Formation.



Satisfaction in phantasy as long as Reality *is completely* excluded.
Fear of Reality.
(Challenge, competition, criticism.)
I want "X."

Another way in which the conscious wish may be gratified is through phantasy. The essential point in phantasy is that it must at all costs avoid reality. We can achieve in phantasy the wish that is impossible of achievement in reality and which, if achieved in reality, would be intolerable. For instance, the child's longing for power and self-importance makes him play the part both of field-marshal, and of editor of the popular press which he has created to exploit his doings. Either of these achievements in reality would involve him in a degree of hard work and responsibility which would be intolerable. If the habit of phantasy is continued his capacity for real achievement will become progressively less. Phantasy is the same as day-dream. Both are an escape from the irksome reality of everyday life. Its material may be the same as imagination, but phantasy is essentially different from imagination in that, whereas phantasy *must remain* dissociated from reality, imagination may be a means towards achieving it. When phantasy becomes real, it is always met with disaster. We should all like to believe that the girl of our dreams is the most beautiful girl in the world, but to see what corresponds to that phantasy in the front row of the chorus and to marry her is to court disaster.

The following is an example of phantasy occurring in a male homo-sexual, aged 23, and represents a day-dream of wish-fulfilment, which was fortunately dissociated from reality.

> "I would have a very famous school, which would be for consumptives, arranged so that they could be naked all day long. I should start with a few boys in a Clinic, who would get on so well that we should become world-famous, so that eventually I would have about 1200 boys who would all be naked. We would have a magnificent building with a fine Chapel surmounted with a Golden Cross, and the motto would be 'The highest and the best.' The boys would sleep naked under ultra-violet light, with their eyes shaded. We should do observations on them as to the effect of frequency of semination upon their work. Semination and homo-sexuality would be encouraged in order to add to the joy of school life, thereby encouraging the power of love. The boys would grow up to be the most important men in the Country and they would look up to me as being the most important of all. They would get into all the places of power and responsibility and would eventually become members of parliament, so that I should be elected as Prime Minister and be the most important person in the world."

Summary.

The conception of "purpose" is essential to understanding the dynamic aspect of modern psychology. Purpose is not necessarily *conscious*, nor is it limited even to *mind*, as was shown by examples of purposive behaviour in the body in conditions both of health and disease.

Not all the "behaviour" of the tissues and parts of the body in disease is purposive, however. Some, of which tremor is a simple example, is only secondary to, or resultant from, a deeper cause. In the latter case, symptomatic treatment, if necessary, is justified. In the former, however, the purposive nature of the behaviour must be remembered, and treatment must remedy the cause. Such purposive disorders are far more commonly found in psychological medicine, and yet in the past they have been treated almost entirely symptomatically, with results necessarily disappointing.

The personality as a whole has certain primary needs, which are sought *purposively*, though not necessarily *consciously*. Most important amongst these are Love, Protection, and Power. These may, under certain circumstances, be achieved through illness and development of symptoms, in which case the illness is wished for not as an end in itself, but as a purposive means to a desired end.

Man is more than the sum of his own experience, and his behaviour is often motivated by past primitive and childish wishes, which are not tolerated by his higher reason and conscience. They are therefore "repressed," but still remain dynamically active, and therefore give rise to "conflict," and often to subsequent symptom formation.

Consciousness is all of which we are aware, but does not contain all our motives. Consciousness as a whole, however, is unified in the way that pleases its own standards by "rationalisation." It therefore looks deceptively complete, and this deception is itself purposive in affording both a self-justification and an organised simplicity and unity. "I am quite sure" usually only means "I want to be sure." Rationalisations are therefore liable to be defended with great emotional intensity, and the latter is usually indicative of the existence of the former.

Purpose or wish fulfilment may evade reality altogether, and achieve the desired end in "phantasy," which is pathological because it is at the expense of a flight from reality. Adaptation is wish-fulfilment through reality, and phantasy is false adaptation. Being a proposive detachment from reality it is a fundamental factor in the development of insanity.

SPECIAL ARTICLES

POST-VACCINAL ENCEPHALITIS.

A REVIEW OF RECENT DATA.

IN an appendix to a further report of the Committee on Vaccination, just issued, appears a translation of a report by Sir George Buchanan presented in May last to the permanent committee of the Office International d'Hygiène Publique. This report has been designed to bring out the principal observations which have been received by the Office International since the expert conference at The Hague in 1926 on the incidence and character of post-vaccinal encephalitis. The countries chiefly affected are the Netherlands and England.

The Netherlands.

Dr. Jitta estimated in May, 1929, that 146 cases had occurred in Holland and that recent data in 1928 pointed to a ratio of 1 case per 5000 vaccinations, with a fatality of 1 in 3. In August, 1929, variola was imported into Holland and energetic measures were taken to secure vaccination on a large scale. At least 77,354 vaccinations and 1,196,465 revaccinations were reported, and these figures have been taken as a basis. There were 52 cases of encephalitis after primary vaccination and 31 after revaccination; of the former group 14, or 26·9 per cent., died, on an average five days after the appearance of the disease, which occurred on the eleventh or twelfth day. The incubation period was shorter after revaccination. Although 16,000 infants under 1 year of age were vaccinated, there was no case among children less than 12 months old. There was one case among 3487 children vaccinated between 1 and 2 years of age, and one case among 815 vaccinated between 6 and 11 years of age. There were 32 cases after revaccination, most of them in persons over 12. The lymph came from Holland itself and three scarifications were made, each ½ cm. long and 2 cm. apart. There was no certain relation between the intensity of the local reaction after vaccination and the occurrence of encephalitis, and in no case was there anything like a generalised vaccinia.

England.

During 1926 and the first nine months of 1927, 40 English cases were considered and 15 of them were eliminated. In the two subsequent years 108 cases were reported and 90 of these were considered to be post-vaccinal encephalitis. During these two years about 576,000 primary vaccinations and 293,000 revaccinations were performed with Government lymph, but during 1929 an unusually large number of vaccinations were done with lymph obtained from commercial firms, and the total number is probably about a million and a half. Of the 90 cases, 54 were in children of 5 to 15 years of age. As had been noticed previously, some large and populous communities where plenty of vaccination was being done entirely escaped encephalitis, while there was a notable grouping of cases in other similar areas. There were four instances of familial incidence, and one case in each family died. The youngest patient was 1 year and 8 months old and the oldest 55 years.

Forty-seven patients recovered completely, but one woman had not completely recovered after six months. There were 42 deaths, of which 28 occurred within a week of the onset and all but one of the remainder within three weeks.

It is therefore possible to say definitely that in Holland and England post-vaccinal encephalitis is essentially a disease of children primarily vaccinated between 5 and 15, although it is not confined to those years and has occurred in revaccinated cases. It would therefore be expected to occur in countries where children are not customarily vaccinated for the first time until they are of school age. It is, however, almost certain to be missed unless the attention of the public health authority is called to the need for its thorough investigation.

Outside Europe.

There is no record of encephalitis in Asia and Africa, despite the enormous numbers of adult vaccinations. Even though the vaccinated individuals might not come under medical attention after the vaccination, it cannot be without significance that no case of encephalitis was heard of after, for instance, 15 million vaccinations in Bengal in 1928.

A special search of the mortality and morbidity statistics of Canada since 1921 has not raised any suspicion of post-vaccinal encephalitis in that country, and it has been observed very rarely indeed in the United States, where a large proportion of the primary vaccinations are performed at the sixth or seventh year. Apparently only 20 cases are on record, and these were of the usual type. No case has been reported in Mexico in the last five years. Central America and South America have no record of a case, although small-pox and vaccination are both common.

No case has been recognised in Australia and there are grounds for believing that this is not due to any oversight. There has, however, been no small-pox during the last two years and the number of vaccinations has therefore diminished, those performed being usually on infants of less than a year old.

Continent of Europe.

In Germany, during the years 1927 to 1929, there were 50 certain cases with 15 deaths. Most of the vaccinations are done in May, June, and October on children of 2 years of age, and most of the cases occurred during these months and in children of that age. The period of incubation appeared to be 11 days. During the three years 1927 to 1929 there were six cases after revaccination and all of them died. In four of the cases no scar from the primary vaccination was visible. In Austria there were 65 cases with 15 deaths after primary vaccination and 7 cases with 3 deaths after revaccination during the years 1925 to 1929. No cases of post-vaccinal encephalitis proper have been notified from Spain, but certain meningeal symptoms were considered to have been connected with the use of neuro-vaccine. Primary vaccinations in Spain are nearly always carried out before the age of 6 months. The data are also negative from Greece, though special attention has been called to the subject and about 800,000 vaccinations were done during 1928 and 1929. Primary vaccination is rarely done in France between the ages of 5 and 15 and, although much attention has been given to post-vaccinal accidents, no case of encephalitis has been reported from 86 departments; of six suspected cases in the four other departments, only two seemed to be genuine. There are no cases known in Belgium or Italy, probably again because vaccinations are usually done on infants.

Norway reports on 28 cases since 1921, 16 of them between the ages of 5 and 10, with 15 deaths. In Sweden the first case was reported at the end of 1927, and compulsory notification was ordered at the beginning of 1929. During that year three cases occurred and two died. The law requires that children should be vaccinated before the end of the sixth year, and they are therefore usually done as late as possible. It has been noted that nervous disorders are not rare after measles, chicken-pox, mumps, and whooping-cough.

No fresh case has been reported in Switzerland since October, 1928. Vaccinations are rare in German Switzerland, and in the French cantons are compulsory before the end of the first year. Between 1921 and 1926 there was an epidemic of small-pox, and between one and one and a half million vaccinations were performed on older children. Five cases of encephalitis resulted in children between 6 and 17 years of age, and there was one death. In Roumania vaccination is regularly done during th first year of life and again at school age and no cas has ever been observed, although a special look-ou has been kept. The same applies to Poland, excep that two cases were reported in 1926. In Portuga no cases occurred during the years 1928 and 1929 The Soviet Republic is taking steps to study th matter very carefully; one case was reported i 1928 and another in 1929, and between eight and nin million vaccinations are done every year. The firs case in Jugo-Slavia occurred in 1929 after a primar vaccination at the age of 3½.

Pathology.

The English Committee on Vaccination has prepare a commentary on the histological study of 25 typica cases. Its findings accord with those in othe countries. The characteristic lesion is a perivascula demyelination affecting in particular some of th vessels of the white matter of the brain and cord, an attended with certain definite tissue reactions amon which the inflammatory ones are often the leas obvious. The lesions are remarkably symmetrica They may be found after comparatively trivial acut infections, and the problem is not confined to pos vaccinal encephalitis alone. There is urgent nee to find some other method of protection again small-pox, as has already been done in the case rabies. Subacute disseminated sclerosis and acut disseminated encephalomyelitis have many path logical features in common, although they can l clearly differentiated; and recently Pette in German has described a case which seems to occupy an inte mediate position between them. Attempts to find virus transmissible to rabbits and monkeys have bee invariably negative. Kling in Sweden demonstrate some round or oval bodies which he regarded a protozoa, but he does not wish to make any decisiv statement.

The rapporteur's impression is that this complica tion of vaccination is a characteristic clinical entity having a parallel in the encephalitis which may follo acute infectious diseases, and that it is most desirabl that fuller data should be obtained about *encephalit post-infectionem*. His review, while showing tha post-vaccinal encephalitis is an important practic problem, enphasises the rarity of its occurrence an supports the view that it should not be allowe to diminish the confidence placed in the use vaccination.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

HEALTH IN THE UNITED PROVINCES.

REPORTS such as that on the health of the United Provinces for 1929, which is now before us, furnish a rejoinder to agitators who charge the present régime in India with callous indifference to public health. The United Provinces of Agra and Oudh, with their population of over 45 million people, can be taken as a fair example of what is being done elsewhere. The area concerned measures about 107,000 square miles. Figures are given with the qualification that registration of vital statistics and reporting of epidemics are defective; but efforts are being constantly made to effect an improvement, and records are more trustworthy than they were 20 years ago. The provincial birth-rate was 24·3 (35·3), the death-rate 24·2 (25·0), the quinquennial average being given in parenthesis for comparison. Infantile mortality is given as 168·6. There are, of course, marked variations in different regions; for instance, the general death-rate was as low as 15·2 in Gonda district, and as high as 75·8 in the city of Lucknow; and infantile mortality varied between 116·3 and the terrible figure of 469·2, Lucknow again holding the high record. It is satisfactory to note, however, that the general death-rate for infants shows an almost uninterrupted decrease from the decennial average for 1901–10, which was 255·0. As might be expected, the urban areas show a much higher rate than the rural—275·7 for the decennium as contrasted with 157·7. The chief causes of mortality are given as "fevers," cholera, plague, respiratory diseases, dysentery and diarrhœa, and small-pox, in descending order of frequency Fevers claimed 810,583 victims, this number being somewhat less than the quinquennial average, and on the rough diagnosis available the overwhelming majority of these deaths were due to malaria; 77,000 were credited to "other fevers," 12,000 to measles, 8000 to enteric, and only some 300 each to relapsing fever and kala-azar.

The Himalayan foothills, and the great marshy district of the Tarai below, which come into the U.P. boundaries, are hotbeds of malaria. Antimalarial work is being carried out on energetic lines, including the filling in of tanks, the re-alignment of canals, and the draining of swamps. School cinchonisation has been extensively employed and its results are shown in a much diminished spleen-rate and in an increase of 20 per cent. in the school attendance figures during the two malaria seasons. The free distribution of cinchona tablets in villages has also had its effect in diminishing mortality and spleen-rate, and even in increasing the birth-rate. Cholera accounted for 50,924 deaths, the ratio being 1·12 per 1000 of population, as contrasted with a quinquennial average of 0·68. This disease is a specially grave problem in the U.P., owing to the fact that several of the great fairs are held within its borders, and that the district of Garhwal is traversed by the pilgrim route to the Himalayan shrines of Badrinath and Kedarnath. In these areas special cholera schemes have to be worked out. During the year under report cases occurred along the Garhwal pilgrim route, but they were kept well under control, and only 30 deaths were registered there. Pilgrims who left the route, however, carried the infection into the interior, where the disease took on a severe epidemic form. Wherever it occurred cholera was dealt with by the usual commonsense quarantine measures, by inoculation (of 93,000 persons), and by the permanganating of wells. The emergency medicinal treatment consisted of kaolin and a mixture of essential oils. From plague there were 37,678 deaths in 1929, as compared with 80,943 in 1928—a welcome decrease. Inoculation is employed, and 131,320 people were inoculated, as contrasted with more than three times as many in the previous year, when there was more call for it owing to the greater prevalence. An intensive campaign of rat destruction was carried on in some cities; more than 400,000 rats were destroyed by one municipality, mostly by trapping. Under the head of small-pox 11,725 deaths were returned, as contrasted with 3012 in 1928, a number almost twice that of the quinquennial mean. In the best vaccinated provinces bad years will occur, but a chart which is given to show the relation of vaccination to small-pox over a number of years ought to convince the most hardened antivaccinator. During this year 1,374,372 primary vaccinations were performed, and of these 94·7 per cent. were successful. Of children under one year 56·1 per cent. were successfully vaccinated. Only one case of encephalitis following vaccination was reported. A vaccine institute is maintained to supply glycerinated lymph.

A large number of travelling dispensaries were in operation during the year and found to be very useful, and the village aid dispensaries in connexion with schools are well spoken of. So popular have they become that the number, which amounted only to 154 in 1928, has now risen to 1199. In connexion with them elementary hygiene is taught, and an attempt is made to get the people to clean up their villages. A feature of the U.P. health service is the provincial hygiene institute, with which is combined the laboratory of the public analyst. The institute is evidently a very live concern. It carries out routine work, such as clinical bacteriology and water examination; conducts classes for the diploma in public health; undertakes the training of visitors in connexion with maternity and child welfare work; and is concerned with investigations of various kinds, and the preparation of material for public health propaganda, including the production of cinema films. One of the institute's most useful functions is the investigation of malaria epidemics, of which it has at present a large programme in hand. The importance of team-work of this description can hardly be overstated.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

PUBLIC HEALTH IN THE FREE STATE.

THE annual report of the Department of Local Government and Public Health of the Irish Free State for 1929, which has recently been issued, contains much interesting information. It is stated that a county medical officer of health has now been appointed in 15 counties. (This number has been much increased since the period covered by the report: there are only four or five counties in the State which are still without county medical officers of health.) Medical inspection of school-children was in operation in Dublin, Cork, and Clonmel, and in the counties of Cork, Kildare, Offaly, and Louth, and arrangements were being made in the cities of Limerick and Waterford and in many of the remaining counties. The first inspections of the school-children have revealed a high rate of decaying teeth, enlarged tonsils and adenoids, and defective vision, while all forms of tuberculous deformities and conditions of crippledom are fewer than anticipated. Dental caries, the most common physical defect, was found in over half the children examined. Eleven per cent. were found in need of the services of an ophthalmic surgeon, and 18 per cent. had enlarged tonsils and adenoids. An increasing number of areas have made use of the School Meals Act. Infant mortality is diminishing, especially in Dublin county borough. Concurrent with this is a diminishing mortality among children between 1 year and 4 years of age. Three county boroughs and 21 counties have adopted schemes for the welfare of the blind. Arrangements for the prevention and treatment of tuberculosis have progressed, but there are still many patients suffering from the disease who do not come within the influence of the measures taken to prevent or cure it. The principal epidemic diseases reported during the year were: Scarlatina (1148 cases), diphtheria (989 cases), enteric fever (304 cases), and typhus (29 cases). Attention is drawn to the continued retention in the county homes of a considerable number of mentally defective persons and of unmarried mothers.

THE LATE DR. HERRON.

Dr. Robert Thomas Herron died on Dec. 30th at his home in Armagh in his sixty-seventh year. He was educated at the Royal School, Armagh, and received his medical education in Dublin, Edinburgh, and Durham. In early life he was associated with many branches of sport and was one of the best sprinters of his time. He was for many years a member of the Tynan and Armagh Hunt Club, and frequently rode his own mount at point-to-point meetings. He was a clever surgeon and was medical officer for the Armagh Board of Guardians, His Majesty's Prison, the Military Depôt, Macan Asylum for the Blind, and Shiel's Institution. Dr. Herron served in the South African War and retired with the rank of major, holding the 1901–02 medal, with four clasps. He also served in the late war. A man of culture, a physician of versatility and resource, a sportsman, a prime mover in every social work, his genial presence will be long missed in County Armagh.

PANEL PRACTICE

A Report on Insurance Practice.

AT a meeting of the Paddington Medical Society to be held at the Great Western Hotel, Paddington Station, next Tuesday evening at 8.45 P.M., a report on national health insurance practice will be presented. The report is the outcome of about a dozen meetings in which a number of practitioners resident or in practice in the Paddington area have taken part. The matters discussed include: (1) a definition of a "normal service" to be rendered in respect of any given capitation rate; (2) the encouragement of the insurance practitioner in the performance of additional and special services beyond the range of this normal service; (3) the difficulties connected with medical certification and, particularly, a statement of causes of increased certification which it is suggested explain the problem and place it to a great extent outside medical control; (4) remedies for the purely medical agents in the causation of excessive certification and prescribing; (5) modifications of administrative and disciplinary control designed to improve the working of medical benefit and the status of the insurance practitioner, and modifications of the terms of service designed to bring the remuneration into more definite relatic with the obligations imposed.

The report is local in the sense that it represen the views of a group of practitioners in Paddingto But it should prove of interest to other insuran practitioners in London who will be welcome at tl meeting. Copies of the report in printed pamphl form may be obtained for 2*s.* 6*d.* on application the hon. secretary of the Society at 23, Westbour Park-road, London, W.2.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lts. H. E. M. Martin and R. L. G. Proctor to Surg. Lt.-Comds.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg.-Comdr. J. B. Ronaldson, V.D., to be Surg.-Ca and Surg. Lt.-Comdr. J. Lorimer, V.D., to be Surg.-Comd

ROYAL ARMY MEDICAL CORPS.

The undermentioned Cols., having attained the age compulsory retirement, are placed on retd. pay: F. Irvine, late R.A.M.C., and L. N. Lloyd, late R.A.M.C.

Lt.-Cols. and Bt. Cols., from R.A.M.C., to be Col Temp. Col. A. C. H. Gray, vice Col. L. N. Lloyd, and Ahern, vice Col. F. S. Irvine.

Lt.-Col. O. Ievers to be temp. Col.

Maj. (temp. Lt.-Col.) W. F. M. Loughnan to be Col., vice Lt.-Col. and Bt. Col. D. Ahern

Maj. (temp. Lt.-Col.) J. J. O'Keeffe to be Lt.-Col., Lt.-Col. and Bt. Col. (temp. Col.) A. C. H. Gray.

Lt.-Col. J. D. Bowie, Reg. Army Res. of Off., to be M whilst re-empld. under Art. 507 (b), Royal Warrant Pay and Promotion, 1926, and relinquishes the rank Lt.-Col.

Maj. and Bt. Lt.-Col. A. D. Fraser to be temp. Lt.-

Maj. A. Irvine-Fortescue to be temp. Lt.-Col.

TERRITORIAL ARMY.

Lt.-Col. (Bt. Col.) P. J. Gaffikin to be Col. and to A.D.M.S., 44th (Home Counties) Div., vice Col. C Ponder vacated.

Capt. D. Ross to be Bt. Maj.

Capt. A. D. Rope (late R.A.M.C.) to be Capt.

N. H. Leslie (late Offr. Cadet, Aberdeen Univ. Cont Sen. Div., O.T.C.) to be Lt.

Supernumerary for service with O.T.C.—Lt. R. J. Pulvertaft (late R. Sussex R.) to be Lt. supern. for s with Med. Unit, Univ. of London. Contgt., Sen. D O.T.C.

ROYAL AIR FORCE.

Wing-Comdr. W. Tyrrell to be Group Capt., and Squa Leader K. Biggs to Wing-Comdr.

Flying Officer D. D. Watson resigns his short ser commission.

MENTIONED IN DESPATCHES.

The name of Capt. A. M. Simson, R.A.M lately attached Sudan Defence Force, has been brou to notice by the High Commissioner for Egypt and Sudan for distinguished services rendered in conne with the operations in the Nuer country during the pe between Dec. 8th, 1927, and Feb. 7th, 1928.

COLONIAL MEDICAL SERVICES.

The following appointments have been made rece by the Secretary for the Colonies: Dr. G. S. Escoff Medical Officer of Health, Jamaica; Dr. H. D. Cro Medical Officer, Kenya; Dr. J. G. Slimon, Health Offi Malayan Medical Service; and Dr. C. H. Howat and J. J. I. Phelan, Medical Officers for Tanganyika Terri and Zanzibar respectively.

West African Medical Staff.—Dr. A. J. Johnson, Med Officer.

HONORARY SURGEONS TO THE KING.

Lt.-Col. J. McPherson, I.M.S., and Maj.-Gen. J. Graham I.M. C.I.E., have been appointed Hono Surgeons to the King.

EXTENSION OF BRENTWOOD HOSPITAL.—T institution is about to be enlarged at a cost of least £10,000 by remodelling the executive offices building a new horse-shoe block on the garden. enlargement is necessitated by the growing pressure u accommodation.

PUBLIC HEALTH SERVICES

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1929 statistics of Belfast and Salford :—

Name of city and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality in childbirth.
Belfast .. .. (415,151)*	*21·4*	*15·6*	*1·40*	*1·05*	*4·3*	*1·9*	*112/33*	67	5·3
Salford .. .. (235,600)	16·6	15·4	1·32	1·32	5·0	1·1	125/—	68	3·8

* Census of 1926. Notified stillbirths per 100 live births—Belfast 2·9, Salford 4·3.

Belfast.

Dr. Charles S. Thomson took over the duties of medical superintendent officer of health on March 1st, 1930, and in his first report submits a comprehensive survey of the public health activities of the city which he hopes will be a foundation for subsequent reports. His first impressions are that Belfast has no serious slum problem and no grave housing question. It is also fortunate in its large number of parks and open spaces. He judges that overcrowding is relatively small, and bases this opinion both on the census returns of 1926 and the experience of his staff derived from visitation for various public health reasons and for routine house-to-house inspection. The water-supply was satisfactory in quality and quantity during 1929, and the possibility of shortage during an excessively dry summer will be removed by the completion of the large reservoir in the Mourne mountains during the next few years. Some of the many rivers and streams in the city are liable to pollution and remedial steps are being taken. Improvements of the sewerage scheme are in progress. In 1897 there were 27,000 privies; now there are only 284, mostly in unsewered outlying districts. The scavenging system is being improved on up-to-date lines. Only 44 smoke observations were made in 1929, but it has been arranged to take 104 observations in each of the four divisions of the city during the current year.

The many satisfactory features of the city from the point of view of environmental hygiene make Dr. Thomson optimistic as to the future, *if attention is* paid to the principles and practice of public health, domestically as well as municipally, and a determined effort is made to educate the public in the matter. There would seem to be no justification, environmentally for example, for the high infant and tuberculosis mortality rates. A scheme for dealing with the former, outlined in the report, includes the appointment of a whole-time medical officer, nine additional health visitors, the establishment of several new centres either to replace those in unsuitable buildings or to serve districts unprovided for, a large increase in free milk for children, and the establishment of an orthopædic scheme.

Salford.

Dr. H. Osborne reports that there was an increase of 65 in deaths from whooping-cough, of 149 from influenza, 165 from bronchitis, and 99 from pneumonia, as compared with 1928. Infant mortality increased from 106 to 125 mainly owing to an epidemic of diarrhœa. Diphtheria was more prevalent, 678 cases with 39 deaths. The type was more severe. Nearly all the cases were admitted to hospital and the case-fatality was 6·4 per cent. The medical superintendent of the hospital, Dr. W. Edge, was asked to immunise the staff at the Salford Royal Hospital, and about 20 general practitioners accepted the invitation to see the methods adopted. Dr. Edge also conducts immunisation clinics at two centres, but the response *is only small as yet.* A "*bed isolation*" ward was established at the hospital in January. 165 cases were admitted and there was no case of cross infection. The up-to-date X ray apparatus has been a great aid to diagnosis at the dispensary.

No great reduction in the tuberculosis mortality in Salford can be expected, Dr. Osborne says, until there is a vast improvement in housing conditions. He issues hundreds of certificates to overcrowded families applying for Corporation houses, but in *most cases without avail; 3000* houses are needed to rehouse the tenants of slums, but further housing provision is also needed to relieve overcrowding. The Health Committee can take no action for overcrowding in the 312 houses let in lodgings, and it is *obvious for lack of space that the new houses needed* cannot be built in the city.

A noteworthy feature of the report is the account of the first two years' working up to March 31st, 1930, of the municipal "ad hoc." V.D. clinic. Judged by every test *it* is an unqualified success. Since the removal from the Salford Royal Hospital the new cases have multiplied fourfold and the attendances tenfold. The staff is being increased to meet the extra work. About half the patients come from outside areas. Thirty-five per cent. of the new cases are non-venereal. The clinic is at the disposal of patients all day and every day. The new cases for last year numbered 2172, but the V.D. medical officer, Dr. E. Tytler Burke, will not be satisfied until *they reach 3000. The proportion of females to males* for syphilis is 1 to 3·4 and for gonorrhœa 1 to 5·9. This may be compared with 1 to 1·6 and 1 to 4·0 respectively for the country as a whole. Dr. Burke is clear that their scheme does not yet touch a sufficient number of women. *Less than half the new cases were* early syphilis—i.e., from primary sero-negative to late secondary. An investigation of the occupation of the new male cases shows that 10·3 per cent. are engaged in road transport and that 16·3 per cent. are seamen. *Dr. Burke considers that the growth* of mechanical transport with long journeys by lorry drivers has given rise to a problem on shore similar to that of the sailor. He suggests that provision should be made for the comfort of these men during their *long journeys. He goes on to point out the danger* of accidents when, as quite commonly happens in his experience, the drivers in charge of vehicles are suffering from grave syphilitic disease of the brain and spinal cord. In May, 1930, the Manchester *Watch Committee brought forward a proposal* to institute a medical test for such drivers. With regard to defaulters, these numbered in 1928–29 33 per cent. and in 1929–30 36 per cent. The follow-up letter to 720 defaulters brought no reply from 38 per cent., and *in 23 per cent.* was returned as wrong address. Nearly 30 per cent. resumed treatment. The male in-patient accommodation of six beds is inadequate, and Dr. Burke recommends 50 beds for men, women, and children at Hope Hospital, Pendleton. The establishment of *a local branch of the British Social Hygiene* Council for propaganda purposes is urged. The clinic is recognised by Victoria University as a teaching establishment and the post-graduate lectures were attended by 40 general practitioners.

The designated Milk Order is regarded as a *dead* letter, the price charged for milk from tuberculin-tested herds being prohibitive. Eighty per cent. of the milk sold is pasteurised, but not according to regulations. Of 453 mixed milks 9·7 per cent. were tuberculous. The milk from Cheshire farms gave a percentage of 10·8 and from Lancashire farms of 9·4. No improvement is expected until routine veterinary inspection is adopted and the farmers notify their cases. The public analyst urges the need for standards for certain classes of foods, notably jam and cheese. Among the interesting samples culled from his report are :—

> A home-made jam contained 42 parts per million of sulphur dioxide, artificially dyed, and made from imported pulp ; two samples of lemon cheese put up in small glass jars tied with parchment paper in imitation of a home-made article (one contained 38 per cent. of water and only 5 per cent. of butter, the other contained no butter but 18 per cent. of margarine) ; a diabetic flour which proved to be ordinary whole flour ; a sample of malt extract and cod-liver oil, containing 3·3 per cent. of cod-liver oil by weight.

An important development of the maternity and child welfare scheme was the opening of two new centres, "admirably suited to their purpose," the first being opened in February by Dame Janet Campbell.

A REVIEW OF SCHOOL MEDICINE IN 1929.

A SURVEY of the reports of school medical officers, many of which have received separate notice in this column, shows a general tendency for education authorities to follow the lead set in the most progressive areas, so that developments like orthopædic schemes, and those dealing with rheumatism, open-air instruction, and even stammering classes will soon come to be usual instead of exceptional. More attention, too, has been directed to sanitation and hygiene of school buildings, many of the newest erections being models of what a school should be.

Another feature of the year was the increased attention given to the pre-school child. The dictum that the elementary schools are "receivers of damaged goods" is being taken to heart, and many reports—e.g., Eccles, Colchester—deal at length with measures taken to prevent damage to the goods. Thus the coördination and coöperation between the school medical service and the general public health, notably the section that deals with maternity and infant welfare, has become more intimate. One step in this direction has been the joint appointment of medical personnel, one or more of the school doctors being also part-time officer of the infant welfare centre. In some county areas the new medical officer of health for a district has been appointed also to inspect the local schools, or the assistant to the county M.O.H. has been allocated to school work. School nurses who are public health visitors see the children at all ages, and school treatment clinics have been thrown open to pre-school children with proved benefit, especially in cases of squint and orthopædic defect. Further, there has been a beginning of the wider development of nursery schools and of nursery classes in the elementary schools.

The spirit of team-work is also seen in the practice, now almost universal, of including in the report of the school medical officer that of the organisers of physical training. Their activities are closely associated with those of the orthopædic staff ; as physical culture becomes more fully recognised as an integral part of education, the less will be the need of formal corrective work and surgical treatment. Several medical officers discuss the report of the Departmental Committee on the mentally defective, and the findings of Dr. E. O. Lewis. The main lesson has not been overlooked—viz., that the mentally defective are closely associated in origin with the backward and subnormal, and these are more numerous and more important—for they are more improvable and better worth improving. The fact is brought out by many investigators that the backward usually have high intelligence quotients, and owe their troubles largely to defects such as deafness, malnutrition, and neurosis. For all of these they need specialised medical care, but nothing has been done to organise such classes under the supervision of expert medical officers ; all that has happened as yet has been an arrest in the provision of new special schools for the mentally defective. As in previous years, there is still far too little accommodation for the epileptic, and scarcely any, apart from London, for victims of encephalitis lethargica.

Research has been carried on to the benefit of those engaged in it—senior medical officers (e.g., Notts) have emphasised this activity as an antidote to the stagnation of routine inspection—and to the advantage of school hygiene and of medical science as a whole. Subjects like the warming and ventilation of school buildings, on which valuable information has been obtained (Torquay, Brecon), are mainly of interest to those concerned, and the merits of ultra-violet ray therapy and artificial sunlight (Leeds), and of special window glass (Smethwick, Glasgow) appeal to a limited medical circle, as do indeed the valuable studies of overstrain and fatigue in scholars and in teachers (Leicestershire, London). Inquiries, however, into rheumatic heart disease (London, Bristol, and others), into the treatment of enuresis (Kent), and of otorrhea (Notts) are worthy of general attention.

Several medical officers find comfort in lookin back over the changes that they have seen in th last two decades. Verminous children were formerl so numerous and their condition so bad that visitor thought of an elementary school as a place of horror now there are some schools without a single ver minous child, and even when, as in the majority there are a few cases, they are so slight as to nee close inspection to detect them. Similarly, thoug progress in healthy dentition is less rapid, it i becoming rare to find a badly septic mouth in school-child, and the percentage of children wit clean mouths and sound teeth is steadily increasin (Sheffield, Cambridge), though many authorities sti need increased dental staff. And, with the sign of progress and development of facilities, there i evident a widening conception of the scope an purpose of school medicine, passing on from th removal of defects and care for the weakly to th education of the children in personal and soci hygiene, enabling them to develop their physique t its full potential capacity, and through the trainin of future parents to raise the level of national healt in years to come.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDE DEC. 27TH, 1930.

Notifications.—The following cases of infectiou disease were notified during the week :—Smal pox, 135 (last week 138) ; scarlet fever, 1567 diphtheria, 1107 ; enteric fever, 13 ; pneumoni 1022 ; puerperal fever, 33 ; puerperal pyrexia, 88 cerebro-spinal fever, 8 ; acute poliomyelitis, 3 acute polio-encephalitis, 1 ; encephalitis lethargic 8 ; continued fever, 1 ; dysentery, 10 ; ophthalmi neonatorum, 50. No case of cholera, plague, typhus fever was notified during the week. Th general lowness of the figures reported during holiday week cannot be taken as indicating an diminution of infectious disease.

The number of cases in the Infectious Hospitals of th London County Council on Dec. 30th–31st was as follows Small-pox, 218 under treatment, 3 under observatio (last week 167 and 4 respectively) ; scarlet fever, 185 diphtheria, 2082 ; enteric fever, 16 ; measles, 98 ; whoopin cough, 131 ; puerperal fever, 22 (plus 8 babies) ; encephaliti lethargica, 121 ; poliomyelitis, 2 ; "other diseases," 6 At St. Margaret's Hospital there were 12 babies (plus mother) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, includin London, there was no death from small-pox o enteric fever, 59 (1) from measles, 11 (2) from scarle fever, 15 (2) from whooping-cough, 33 (8) from diphtheria, 57 (10) from diarrhœa and enteritis unde two years, and 59 (15) from influenza. The figure in parentheses are those for London itself.

Seventeen deaths from measles occurred at Liverpool 9 at Bristol, 8 at Hull, 4 at Grimsby, 3 each at Birmingham Cardiff, and Swansea. Four fatal cases of diphtheria wer reported from Liverpool, 2 each from Ilford, Smethwick, Coventry, Derby, and Manchester. Diarrhœa accounted for 6 deaths at Birmingham and at Liverpool, 3 each at Birkenhead and Manchester.

The number of stillbirths notified during the week was 216 (corresponding to a rate of 51 per 1000 births), including 21 in London.

DIPHTHERIA IN SMETHWICK.

An epidemic of diphtheria in this county borough has severely strained the available accommodation. The number of notified cases began to rise about the middle of September, and from the week ending Sept. 13th to that ending Dec. 27th 168 cases were reported, the highest number in any one week being 26, during the week ending Dec. 20th. The epidemic arose in the most densely populated ward of the borough where overcrowding renders the isolation of contacts difficult or impossible. The type of infection has been severe, for the most part faucial; in three laryngeal cases tracheotomy was performed. There have been 19 deaths during the period mentioned, a case mortality of 11·3 per cent. The 24 beds reserved for diphtheria cases in the local isolation hospital were quite inadequate, but the neighbouring authorities of Birmingham (where the prevalence is not excessive) and West Bromwich were able for some time to deal with the excess cases. As the epidemic spread, accommodation was increased by emptying the tuberculosis pavilion and opening another ward for diphtheria, thus increasing the number of beds to 45. At the present time all these beds are full and a number of Smethwick patients are being treated at Birmingham, West Bromwich, and Halesowen and Stourbridge Joint Isolation Hospital. The usual precautionary measures were adopted and a propaganda campaign to induce the public to seek protection by toxoid-antitoxin inoculation is having good success. Considerable numbers are being immunised at the welfare centres, school clinics, and at the public health department.

The Registrar-General informs us that the certified cause of death of the boy belonging to Dagenham U.D. (see THE LANCET, Dec. 27th, 1930, p. 1429) was: (1*a*) acute myocarditis due to (*b*) diphtheria; (2) smallpox, not vaccinated. No post-mortem.

OBITUARY

AMY HODGSON, M.D., D.P.H. Liverp., M.R.C.P. Lond.

Dr. Amy Hodgson, who died in London on Dec. 19th at the age of 45 years, had devoted herself without stint to the welfare of babies and children. The daughter of Joseph Uttley Hodgson, she was educated at Liverpool High School and University, qualifying there in the middle of the war period and taking the higher distinctions at a later date. After acting as house physician to the Liverpool Royal Infirmary, she became a recruiting medical controller of Queen Mary's Auxiliary Corps, and was mentioned for her services. In 1921, after taking the D.P.H., she was assistant medical officer of health at Huddersfield. A study of vitamin deficiency in relation to the development of rickets, published in our columns at this time, was of a type commoner now than it was then. After a survey of the work of Mellanby, Corry Mann, Dalyell, and others, and an analysis of 120 cases of rickets observed at infant welfare clinics in Liverpool, she came to the conclusion that there must be some common determining factor, unrevealed by ordinary clinical or bacteriological evidence. Dr. Hodgson herself believed she had found sufficient indication of a lowering of alkali reserve in cases of active rickets. Her later publications were of a more general character. She resigned her appointment at Huddersfield to take a resident post at the Infants Hospital in Westminster, combining this with charge of a welfare centre at Caversham-road and a clinical assistantship at Great Ormond-street.

Dr. Eric Pritchard writes: "I first met Dr. Amy Hodgson in 1922, when I entered into correspondence with her about her work in Liverpool on acidosis in children and its association with rickets. Subsequently, I invited her to take part in a discussion at a London medical society on the same subject, and on this occasion, knowing her resourcefulness and many-faceted knowledge, I made her a tentative offer to come to London and help me to reorganise the Infants Hospital, to which I had just been appointed medical director. At that time the fortunes and prospects of the hospital were not very bright, partly on financial grounds and partly owing to the disrupting effects of the war. Although at that time Dr. Hodgson was assistant medical officer of health at Huddersfield under Dr. S. G. Moore enjoying a comfortable salary and congenial work, she welcomed my proposal as an opportunity of engaging in the clinical work which attracted her, although it meant financial sacrifice. There was then no residential staff, no pathologist, and no dispenser at the hospital, but the prospect of fulfilling all these offices had no terrors for her. She faced all difficulties and triumphed over them and, in spite of many routine duties, still found time to pursue in the research laboratory the investigations on acidosis begun in Liverpool. In September of the following year, when improved resources made it possible to appoint a resident medical officer, Dr. Hodgson became registrar and pathologist, which post she held until the end of 1926, when she was taken seriously ill and resigned her connexion with the hospital. From this illness she never properly recovered, although she made heroic efforts to take up the threads of her work elsewhere. Had she enjoyed better health I feel assured that she would have made a considerable name for herself as a pædiatrician."

EDWARD HENRY BALDOCK, M.R.C.S. Eng.

Dr. Baldock, who died at Whitchurch, Herefordshire, on Dec. 22nd, after a short illness, had retired two years ago from a busy practice in Hereford extending over 24 years. Qualifying M.R.C.S. from Guy's Hospital in 1891, he went out to Korea as medical officer to the Customs and to the British Legation at Seoul. After his marriage to a Canadian medical graduate, he travelled, with his wife, in China and Japan, where they both rendered medical service during the Boxer trouble and the Russo-Japanese War. Returning to England in 1904, he succeeded to the practice of Dr. J. B. Fitzsimons at Hereford, becoming city police surgeon and medical officer to the isolation hospital. During the war he was one of the superintendents of the Beechwood Convalescent Hospitals. In many directions, social and philanthropic, he was supported by his wife who was for 15 years a poor-law guardian. Both were keen musicians, Dr. Baldock being an accomplished violinist and a leading member of the local orchestral and choral societies.

CORRESPONDENCE

FIBROSITIS: ITS CAUSATION AND TREATMENT.

To the Editor of THE LANCET.

SIR,—The importance of the causation and treatment of fibrositis has been clearly shown by the paper by Sir Thomas Horder at the Chelsea Clinical Society,[1] and the speeches which were made by some of those present. It would not be advantageous in the space at my disposal to discuss all the possible causes of fibrositis, but as there appears to be a doubt in the minds of some as to the value of bacteriological examination and treatment, I am sending this record of my personal experience which should be helpful.

In 1926 I travelled through from London to Cannes by the usual route, and arrived there about midday on Jan. 19th. There was nothing unusual to mark the journey and my health appeared to be normal on the day of arrival. On the following morning, after a good night's rest, I awoke about 7.30 feeling that my hands were uncomfortable. They were both generally swollen and stiff, but not painful. The swelling was œdematous, most marked about the joints of the fingers, and in the palms of the hands, and there was little difference between the two hands. There was no redness but slight tenderness, and I was able to dress slowly without assistance. Temperature about 100°–101°, pulse 70–80, somewhat irregular. As there was no improvement in the general condition of slight fever, whilst palpitation was readily induced, the advice of a medical friend was obtained a few days later, who diagnosed it as "rheumatic gout" or "gout." During a stay of six weeks in Cannes there was some improvement in the general swelling of the hands, but it became more evident that the flexor ligaments of the fingers (not thumbs) and the palmar fasciæ were the most affected. The general health was indifferent, there being frequent cardiac palpitation on exertion and also when sitting quietly. The medicine prescribed relieved the general malaise, but did not arrest the palpitations. The temperature became normal after the first ten days. After return to town, although no cause was to be discovered, treatment was of advantage inasmuch as it relieved symptoms but did not effect improvement in the appearance of the joints, whilst the palmar fasciæ were becoming more typical of the condition recognised as Dupuytren's contraction. Some months later, progress being unsatisfactory, it was suggested that bacteriological examination should be made of the intestinal ejecta. This was done and a variety of Morgan's bacillus isolated. From this a vaccine was made and two injections given, at an interval of seven days. Improvement followed, and became more evident after a third injection. The general health improved, palpitation no longer caused trouble, and the swelling of the hands and joints diminished, leaving the fingers somewhat flexed. Meanwhile the fasciæ of the palms of the hands showed some irregular, nodular thickening with contraction especially on the right side. Here was an instance of so-called "rheumatic gout," which was really a fibrositis of the ligaments of the fingers and palmar fasciæ followed by a typical "Dupuytren's contraction" of the palmar fasciæ. The fact that it was arrested, and unpleasant symptoms cured, after discovery of its bacterial origin, is of much interest to me, especially as it was a personal experience.

In 1893 THE LANCET[2] published a paper for n on Some Unusual Conditions of the Hands. In th communication, after mentioning a very advanc case of Dupuytren's contraction, I ventured to expre my agreement with the suggestion made previousl by Mr. William Anderson in his Hunterian Lectur at the Royal College of Surgeons,[3] who when discussin the causation of this form of contraction of tl palmar fascia, suggested the possibility of bacteri infection. Not long after my paper was publishe I received a letter from an eminent physician (date April 9th, 1893), which is still in my possession, i which the following comments were made:—

> "Long-continued observation has convinced me of tl fact that Dupuytren's contraction is a disorder almost, not entirely, confined to persons of gouty inheritance . . when I speak of gout I am not thinking of uric acid. Th bacterial theory of Dupuytren's finger, &c., I believe to l utterly absurd."

It is not often that one can confirm so definitely th value of a suggestion, as in this instance that o Mr. Anderson, and my case shows the importanc of a more regular and thorough bacteriologica examination. Dupuytren's contraction is a ver crippling deformity and one in which surgery has no yielded results which can be considered satisfactory The desirability for publication of this observation i strengthened by the following paragraph in th recently published third edition of one of our bes known works on surgery,[4] in which, when speaking o this form of contraction of the palmar fascia, it i *stated*:—

> "In some instances this is hereditary, while there is n doubt that a gouty or rheumatic tendency plays a par in it; many other causes have been assigned to it, such a syphilis and local septic infections, but there is no evidenc of these."

I am hoping that the institution of the special clinics for the treatment of "rheumatism" will dc much to differentiate the diseases now grouped unde this heading. An early and thorough investigation even in comparatively mild cases, should include a bacteriological examination, not only of probable causes, such as suppurating discharges, but also of intestinal ejecta.[5] Unless this is done there will be many cases which will not be properly treated before the changes in, and surrounding, joints are intractable and crippling.

I would like to see the results of the full bacteriological examination of a series of the sufferers from lumbago and sciatica. I have seen pyorrhœa satisfactorily treated in a case of painful joints with some swelling and slight temperature, but relief was not obtained until after X ray examination had revealed an abscess at the apex of a tooth which was apparently healthy, and this tooth was extracted. Rapid recovery followed. Again, in a case of fibrositis with limited pyorrhœa this was regarded as the cause, and treatment carried on for months with but slight improvement. A variety of Morgan's bacillus was found when search was made for it, but the patient is left with deformed and stiffened hands and feet, which localised treatment has alleviated but to a limited extent.

I am, Sir, yours faithfully,

WILLIAM HY. BATTLE.

ACUTE MYELOGENOUS LEUKÆMIA.

To the Editor of THE LANCET.

SIR,—The interesting cases recorded by Dr. Easton in your issue of Dec. 27th, 1930 (p. 1394), are so valuable a contribution to the subject that I am tempted to break a friendly lance with him over the interpretation thereof. The cases which Dr. Easton describes are all good examples of acute myeloblastic leukæmia. In this group the predominant initial symptom is always a sloughing throat, and high leucocytosis and enlargement of the spleen are usually absent because death occurs before these have had time to develop. The blood picture, incidentally, is identical with that found in the final stage of myeloid leukæmia of the chronic type.

The conception of septic infection was, I believe, the first explanation put forward of the pathology of myeloid leukæmia; at all events it has appeared on the stage intermittently for about half a century. It is very plausible, but there are many difficulties in its adoption, and I do not feel that Dr. Easton's cases really support the contention that coccal infection is the cause rather than a concomitant of the leukæmia. Apart from the usual arguments that *hæmolytic streptococci* can be found in almost every sloughing throat, and in the fauces of many apparently healthy people, that infection of experimental animals therewith gives rise to a definite blood picture which is not that of leukæmia, and that if we except the infectious leucosis of fowls which is a disease sui generis leukæmia has never been induced by inoculation, there are some additional points against the infective theory to which I would draw attention.

In normal human beings and in cases of septic infection the administration of a leucocytic stimulant such as sodium cinnamate or nucleinic acid is followed by a polynuclear leucocytosis without primitive forms; in leukæmia no such response occurs. Similarly, the injection of a T.A.B. vaccine gives rise to an increase in the antibody titre to these organisms; in leukæmia this is absent. Primitive granular cells do not appear to be phagocytic or to be capable of forming antibodies. I have frequently used these tests in the diagnosis of doubtful cases of leukæmia. Recently Knott and Watt (*Brit. Med. Jour.*, Dec. 13th, 1930) have shown that the proportion of phagocytic cells in the blood is a valuable guide to the utility or otherwise of deep X ray therapy in the treatment of leukæmia. The explanation of the sloughing throat and other septic manifestations would appear to be that in leukæmia the bactericidal properties of the blood are so markedly diminished that streptococci and any other bacteria gain an easy hold on the patient. Sepsis is, therefore, the result and not the cause.

In practice the conception of sepsis as a cause of leukæmia is not without danger. In a case which I saw in consultation some time ago a dental surgeon was accused of having caused leukæmia by extraction of teeth from a septic mouth. The patient was suffering from acute myeloblastic leukæmia and it was only the blood picture that saved the surgeon from a threatened action by the relatives. We have difficulties enough in coping with the diagnosis and treatment of acute septic infections without having leukæmia added to our pitfalls.

To my mind the chief difficulty in understanding leukæmia lies in the fact that the patients are so seldom seen before the characteristic clinical signs and blood picture are well established, and yet the disease must obviously start, as it were, from scratch. I would, therefore, with Dr. Easton, plead for the publication of more acute cases, and this would be easier if the blood were examined histologically, as it should be, in all cases of acute sore-throat and pyrexia of unknown origin. Until then, however, I advocate research rather than the restatement for which he calls. It is as valuable to determine what is not, as what may be.

I am, Sir, yours faithfully,
A. KNYVETT GORDON.

Bedford-square, W.C., Dec. 27th, 1930.

PASTEURISATION OF MILK.

To the Editor of THE LANCET.

SIR,—As one of the 50 members of the tuberculosis study group which visited Canada this year, the predominating feature to me was the results obtained by pasteurisation. In a document entitled Some Facts Concerning the Tuberculosis Situation in Toronto, given to the group by the Public Health Authorities, there appears the following:—

> "Ranking high among the preventive measures employed against tuberculosis is the city milk pasteurising programme, effective since 1914, under the terms of which the total milk-supply with the exception of less than 1 per cent. is adequately pasteurised under official supervision. The very small quantity not pasteurised and sold under conditions warranting its certification as defined by law. *As a result bovine tuberculosis presents no problem in Toronto.*"

I therefore was delighted to see the letter of Lord Dawson and his eminent colleagues. If Colonel Maddock lived in a Utopian country with Utopian cows and farmers, we would agree with his academic letter. Unfortunately, we do not. At Winsley sanatorium we have always pasteurised our milk and they have always done so at King Edward VII. Sanatorium, Midhurst. What we all want is a practical way of reducing tuberculosis and, as Lord Dawson points out, no one wants to put the clock back.

I am, Sir, yours faithfully,
J. D. MACFIE.

Winsley Sanatorium, near Bath, Jan. 6th, 1931.

To the Editor of THE LANCET.

SIR,—One important point has been omitted in the discussion of Lord Dawson's manifesto on the pasteurisation of milk. While it can be admitted that any damage done to the vitamins in the process of pasteurisation can be made good by the addition of concentrates to the diet, it is not so easy to make up for the loss of soluble calcium. The work of Daniel and Stearns has demonstrated that children fed on pasteurised milk exhibit a negative calcium balance in some cases in contra-distinction to children fed on raw or dried milk. Work in this country is being carried out on the gain in weight of infants fed on Certified and pasteurised milk. The children fed on unpasteurised milk show a very definite advantage over those fed on pasteurised milk. Before the profession as a whole endorses this manifesto every precaution should be taken to ensure that the best method of providing a cheap, clean milk for children is provided by the process of pasteurisation.

I am, Sir, yours faithfully,
Bristol, Dec. 31st, 1930. FRANK BODMAN.

A HOME AT SAN REMO FOR INVALID LADIES.

To the Editor of THE LANCET.

SIR,—I want to bring to the notice of your many readers a home for invalid ladies of limited means, who earn their own living, situated [illegible] Remo, Italy, a spot which is considered [illegible] best all-round climate on the Riviera. The Villa Emily was built by an English artist for his own use and is a commodious house in a large sheltered garden. All the rooms face south and wide verandas run almost the entire length of the two floors. The object of the institution, which was started over 50 years ago and deserves to be better known, is to provide a comfortable home for ladies in ill-health, who need a winter in a warm sunny climate to fit them once again for their duties. It is under the patronage of Princess Beatrice, is run by an English committee, and is in the charge of an experienced trained matron with trained nurses under her. The home has been extensively renovated and has central heating. Each lady has to pay £2 a week. This sum is quite inadequate to cover expenses and the annual deficit is made up by generous friends. Medical attendance and nursing are given free.

I am, Sir, yours faithfully,

San Remo, Dec. 15th, 1930. L. N. HESKETH BIGGS.

"HAPPY MARRIAGES."

To the Editor of THE LANCET.

SIR,—The question whether most marriages prove, in the long run, happy or unhappy is, nowadays, a popular subject for discussion. The protagonists on each side argue hotly but base their arguments, apparently, either on the broadest generalisations or else on a very limited personal experience. One reads, for example, of a gynæcologist who says that "in his experience" most marriages are unhappy. May I suggest that a specialist is hardly the person to be very familiar with the normal? His work deals entirely with the abnormal. It seems that the general practitioner, who sees a good deal of the families in his practice in health as well as in disease and who knows the intimate secrets which patients do not readily disclose to specialists, is perhaps the only person with sufficient and unbiased knowledge to supply exact information on this subject.

It would, I think, be of considerable value to students of social problems and writers on morals if sufficient data could be obtained. I have recently examined all the names of married couples appearing in the books of my practice and subjected them to a critical analysis. Omitting all those whom I do not know with sufficient intimacy, and also all who have not been married longer than four years, I find there are 188 couples about whose married lives I have definite information as to their happiness.

If these are divided into four groups: (*a*) those who are fundamentally happy; (*b*) those who are moderately happy—i.e., whose happiness depends on the favour of fortune; (*c*) those who are moderately unhappy—i.e., whose unhappiness might be turned into happiness by material circumstances; (*d*) those who are fundamentally unhappy—that is to say, whose unhappiness is incurable and beyond mere material conditions; I obtain the following: (*a*) 50 per cent.; (*b*) 14·5 per cent.; (*c*) 15·5 per cent.; (*d*) 20 per cent. These figures, I should explain, are derived from a middle-class surburban practice.

I should be much interested if others in general practice in different social spheres would supply similar analyses. By such means, and by them *only*, can definite and fairly reliable information on this interesting subject be obtained. I may add that I was very much surprised by my figures as I had got the impression that most marriages were a failure—*which shows the danger of forming opinions* on insufficient data!

I enclose my card and remain, Sir,

yours faithfully,

Dec. 29th, 1930. W.

MEDICAL NEWS

Royal College of Surgeons of England.

The following lectures will be delivered at the College at 5 P.M. on the days indicated: Jan. 19th, Mr. Victor Bonney: The Results and Technique of Myomectomy; 21st, Mr. J. Basil Hume: The Pathology of Diaphragmatic Hernia; 23rd, Mr. J. W. Tudor Thomas: Successful Grafting of the Cornea in Rabbits; 26th, Mr. D. H. Patey: The Pathological Basis for the Treatment of Varicose Veins by Injections, and its bearing on the problems of Thrombosis: 28th, Mr. J. Paterson Ross: The Treatment of Cerebral Tumours with Radium, with an account of Experiments made to study the effects of Radium upon Cerebral Tissue; 30th, Dr. Donald Hunter: Changes in the Bones in Hyperparathyroidism and Hyperthyroidism; Feb. 2nd, Prof. H. H. Woollard: The Potency of the Pharyngeal Entoderm; 4th, Mr. T. P. Dunhill: Malignant Disease of the Thyroid Gland—the relation of the incidence and spread to its embryology and prognosis.

University of London.

Prof. Joseph Barcroft, F.R.S., is giving three lectures on the Constancy of the Internal Environment: its Evolution and Purpose, at King's College, Strand, on Mondays, Jan. 26th, and Feb. 2nd and 9th, at 5.30 P.M.—The course of ten lectures on Comparative Physiology to be given by Mr. G. P. Wells, at University College, Gower-street, begins at 5 P.M. on Friday, Jan. 16th.—Prof. G. Elliot Smith, F.R.S., will give a public lecture on the Peking Man at University College on Thursday, Jan. 15th, at 5.30 P.M.—On March 16th and 17th Prof. B. Brower, of Amsterdam, will lecture at University College on the Central Nervous System.

London School of Hygiene and Tropical Medicine.

The course of special lectures given at this school during the autumn will be resumed next week. Particulars will be found in our Medical Diary.

International Congress of Radiology.

The third meeting of this congress will be in Paris from July 26th to 31st. The subjects to be discussed are th radiological examination of the urinary apparatus, and o the mucosa of the digestive tube, the pre- and post-operativ treatment of cancer of the breast by radiation (excep recurrences and metastases), and radiotherapy an diathermic electrotherapy for inflammatory diseases. Th offices of the congress are at 122 rue la Boëtie, Paris VIII.e

Charing Cross Hospital Post-graduate Course.

If enough support is received, the staff of Charing Cros Hospital will hold a post-graduate course at the medica school on Sundays from Jan. 18th. The lectures will b given on ten consecutive Sunday mornings and a fee o one guinea will be charged to cover expenses. Those wishin to attend are asked to communicate at once with the secretar of the medical school, 62, Chandos-street, London, W.C. 2 The first two lectures (on Jan. 18th) will be by Mr. Jenning Marshall (10.30 A.M.) on the Diagnoses and Treatment o Urinary Infections, and by Dr. Everard Williams (11.45 A.M. on the Antenatal Care of Expectant Mothers.

Neurological Post-graduate Demonstrations.

A series of monthly clinical demonstrations for practitioners will be given at the Hospital for Epilepsy and Paralysis, Maida Vale, W. 9, by the members of the honorar medical staff, beginning on Thursday, Jan. 22nd, at 3 P.M. when Dr. Wilfred Harris will demonstrate. Tea will b provided, and it will be a convenience if those intending t be present will send a card to the Secretary.

Society of Radiographers.

This Society will hold its annual dinner at the Florenc Restaurant, Piccadilly Circus, on Friday, Feb. 13th, a 7.15 for 7.30 P.M.

all-round climate on the Riviera. The Villa Emily was built by an English artist for his own use and is a commodious house in a large sheltered garden. "HAPPY MARRIAGES."

To the Editor of THE LANCET.

SIR,—The question whether most marriages prove, in the long run, happy or unhappy is, nowadays, a popular subject for discussion. The protagonists on each side argue hotly but base their arguments, apparently, either on the broadest generalisations or else on a very limited personal experience. One reads, for example, of a gynæcologist who says that "in his experience" most marriages are unhappy. May I suggest that a specialist is hardly the person to be very familiar with the normal? His work deals entirely with the abnormal. It seems that the general practitioner, who sees a good deal of the families in his practice in health as well as in disease and who knows the intimate secrets which patients do not readily disclose to specialists, is perhaps the only person with sufficient and unbiased knowledge to supply exact information on this subject.

It would, I think, be of considerable value to students of social problems and writers on morals if sufficient data could be obtained. I have recently examined all the names of married couples appearing in the books of my practice and subjected them to a critical analysis. Omitting all those whom I do not know with sufficient intimacy, and also all who have not been married longer than four years, I find there are 188 couples about whose married lives I have definite information as to their happiness.

If these are divided into four groups: (*a*) those who are fundamentally happy; (*b*) those who are moderately happy—i.e., whose happiness depends on the favour of fortune; (*c*) those who are moderately unhappy—i.e., whose unhappiness might be turned into happiness by material circumstances; (*d*) those who are fundamentally unhappy—that is to say, whose unhappiness is incurable and beyond mere material conditions; I obtain the following: (*a*) 50 per cent.; (*b*) 14·5 per cent.; (*c*) 15·5 per cent.; (*d*) 20 per cent. These figures, I should explain, are derived from a middle-class surburban practice.

I should be much interested if others in general practice in different social spheres would supply similar analyses. By such means, and by them only, can definite and fairly reliable information on this interesting subject be obtained. I may add that I was very much surprised by my figures as I had got the impression that most marriages were a failure—which shows the danger of forming opinions on insufficient data!

I enclose my card and remain, Sir,

yours faithfully,

Dec. 29th, 1930. W.

MEDICAL NEWS

Royal College of Surgeons of England.

The following lectures will be delivered at the College at 5 P.M. on the days indicated: Jan. 19th, Mr. Victor Bonney: The Results and Technique of Myomectomy; 21st, Mr. J. Basil Hume: The Pathology of Diaphragmatic Hernia; 23rd, Mr. J. W. Tudor Thomas: Successful Grafting of the Cornea in Rabbits; 26th, Mr. D. H. Patey: The Pathological Basis for the Treatment of Varicose Veins by Injections, and its bearing on the problems of Thrombosis: 28th, Mr. J. Paterson Ross: The Treatment of Cerebral Tumours with Radium, with an account of Experiments made to study the effects of Radium upon Cerebral Tissue; 30th, Dr. Donald Hunter: Changes in the Bones in Hyperparathyroidism and Hyperthyroidism; Feb. 2nd, Prof. H. H. Woollard: The Potency of the Pharyngeal Entoderm; 4th, Mr. T. P. Dunhill: Malignant Disease of the Thyroid Gland—the relation of the incidence and spread to its embryology and prognosis.

University of London.

Prof. Joseph Barcroft, F.R.S., is giving three lectures on the Constancy of the Internal Environment: its Evolution and Purpose, at King's College, Strand, on Mondays, Jan. 26th, and Feb. 2nd and 9th, at 5.30 P.M.—The course of ten lectures on Comparative Physiology to be given by Mr. G. P. Wells, at University College, Gower-street, begins at 5 P.M. on Friday, Jan. 16th.—Prof. G. Elliot Smith, F.R.S., will give a public lecture on the Peking Man at University College on Thursday, Jan. 15th, at 5.30 P.M.—On March 16th and 17th Prof. B. Brower, of Amsterdam, will lecture at University College on the Central Nervous System.

London School of Hygiene and Tropical Medicine.

The course of special lectures given at this school during the autumn will be resumed next week. Particulars will be found in our Medical Diary.

International Congress of Radiology.

The third meeting of this congress will be in Paris from July 26th to 31st. The subjects to be discussed are the radiological examination of the urinary apparatus, and of the mucosa of the digestive tube, the pre- and post-operative treatment of cancer of the breast by radiation (except recurrences and metastases), and radiotherapy and diathermic electrotherapy for inflammatory diseases. The offices of the congress are at 122 rue la Boëtie, Paris VIII.e

Charing Cross Hospital Post-graduate Course.

If enough support is received, the staff of Charing Cross Hospital will hold a post-graduate course at the medical school on Sundays from Jan. 18th. The lectures will be given on ten consecutive Sunday mornings and a fee of one guinea will be charged to cover expenses. Those wishing to attend are asked to communicate at once with the secretary of the medical school, 62, Chandos-street, London, W.C. 2. The first two lectures (on Jan. 18th) will be by Mr. Jennings Marshall (10.30 A.M.) on the Diagnoses and Treatment of Urinary Infections, and by Dr. Everard Williams (11.45 A.M.) on the Antenatal Care of Expectant Mothers.

Neurological Post-graduate Demonstrations.

A series of monthly clinical demonstrations for practitioners will be given at the Hospital for Epilepsy and Paralysis, Maida Vale, W. 9, by the members of the honorary medical staff, beginning on Thursday, Jan. 22nd, at 3 P.M., when Dr. Wilfred Harris will demonstrate. Tea will be provided, and it will be a convenience if those intending to be present will send a card to the Secretary.

Society of Radiographers.

This Society will hold its annual dinner at the Florence Restaurant, Piccadilly Circus, on Friday, Feb. 13th, at 7.15 for 7.30 P.M.

NOTES, COMMENTS, AND ABSTRACTS

OMEN MENTAL DEFECTIVES AND CRIME:

A PRACTICAL STUDY.*

y LETITIA FAIRFIELD, C.B.E., M.D. EDIN., D.P.H., BARRISTER-AT-LAW.

MUCH of the prevalent discussion on problems of ental deficiency is purely theoretical and has little elation to the human material with which it has to eal. It may therefore be of some interest to study ne aspect of the question—the relation of mental eficiency in women to crime—from a practical angle, nd to inquire how far certain pre-conceived notions re supported by facts. A survey has therefore been ade of all the defective women notified to the local uthority as having come into definite conflict with he law over the five years 1925–29 in the London rea where, as is generally acknowledged, the Mental eficiency Acts are actively in operation.

The Mental Deficiency Acts, 1913 and 1927, place n the local authority an obligation to ascertain such ental defectives in their areas as are: (1) neglected r delinquent; (2) under the care of the poor-aw, having given birth to an illegitimate child; (3) ll-treated by persons in charge of them; (4) defectives nder the age of 21 whose parents wish them to eceive further training; or (5) children, about to leave special school, who have been notified by the ducation authority as needing further care. Where he education authority has faithfully performed its tatutory duty of ascertaining which children in its chools are mentally deficient and providing them with a suitable education, the vast majority of efectives in a district will come under the care of the uthorities under Clauses (4) and (5)—i.e., before any ocial disaster has occurred. We are here concerned, owever, with the handful of women and girls who ame to notice in the capacity of delinquents.

Ascertainment among Delinquents.

The procedure in London is as follows. Any prisoner who arouses suspicion of mental abnormality, either by her behaviour at the time of arrest or in court, or who is already known to the police or probation officer as mentally weak, may on the order of the learned magistrate be remanded in custody for a report on her state of mind by the prison doctor. If the doctor reports that in his opinion the woman is certifiable under the Mental Deficiency Acts, she is on her next appearance in court again remanded in order that the responsible local authority (in London, the County Council) may be asked whether it will accept and deal with the case. The L.C.C. medical officer then visits the prison and examines the defective, and if he concurs in the diagnosis he gives evidence to that effect when the prisoner is again brought before the court. The learned magistrate may deal with the case under Section 8 of the Mental Deficiency Act, 1913—i.e., he may postpone passing sentence and direct that a petition be presented to a judicial authority with a view to obtaining an order that the defective be sent to an institution or placed under guardianship or, in lieu of passing sentence, he may himself make such an order, the latter being the more usual and simpler procedure. This clause applies only to persons convicted of an offence punishable, in the case of an adult, with penal servitude or imprisonment. Section 9 of the Act empowers the Secretary of State to transfer any prisoner found to be defective while undergoing sentence either to any institution where managers are willing to receive them, or to guardianship. This section is useful for such defective prisoners—fortunately rare—as have escaped the notice of the court before or during trial.

For certification the prisoner must come within one of the four categories of the Mental Deficiency Acts—i.e., idiot, imbecile, feeble-minded, and moral defective—and it must be established to the satisfaction of the court that the defect arose before the age of 18 years. The diagnosis of mental status is made by the aid of standardised intelligence tests, some modification of the original Binet-Simon scale, such as Burt's London scale or the Stanford revision. Simple performance tests and other tests such as the Porteous series are also used. Much has been said in ridicule of psychological tests, but without their use the whole discussion of mental deficiency as a social problem would become meaningless. No two persons could agree what class of individuals they were talking about, nor could they convey in words the defective's mental relationship to normal persons. It should be—but is not—unnecessary to point out that the diagnosis is not made by the tests but by the person who uses them. They are servants, not masters. In a recent *cause célèbre* a distinguished alienist was referred to contemptuously by counsel as a "mental certifier." He retorted with dignity, "I am not a 'certifier,' I am a physician," and it is on that basis alone that every doctor should give evidence.

Learned magistrates differ considerably in the evidence they require as to the essential point of defect "before the age of 18"; usually if it proves impossible to ascertain the early history of the patient they accept a statement from the doctor that in his opinion the defect is such that it *must* have existed before 18 years; as an expert witness he is entitled to draw such an inference from his observation of the patient. Nowadays this is rarely a stumbling-block in practice, as the tests at our command are usually adequate to make a diagnosis clear, but the doctor may sometimes be in difficulty over an elderly person of obscure antecedents whose mental enfeeblement might well be attributable to the mild dementia induced by drink and privation. It is important here to adhere to the terms of the Statute, even at the price of occasionally losing hold of a patient who would unquestionably benefit by care and control.

The conditions of the examination are such as to give every possible chance to the prisoner. Recently a magistrate in a case in which I was giving evidence expressed his surprise and pleasure that the prisoner had been seen by two specialists. In fact all prison cases are seen by at least two independent experts, the prison doctor and the L.C.C. medical officer; the notes are discussed by the latter with the head of the department and a further opinion can be obtained if there is the slightest doubt. The prison authorities kindly permit a prolonged interview with the prisoner under most favourable conditions, and the certifying officer has the benefit of information from the experienced staff who have had the woman under observation, and of access to previous records. A school history has usually been obtained by the prison authorities; if not, it is procured later, if at all possible. In London the certifying officers are also dealing with school-children and have access to the schools and all reports on school-children, normal and subnormal. The records of ex-special school-children go back over 30 years.

If the woman is considered certifiable, a trained social worker on the local authority's staff visits or corresponds with the home and with any recent employer or social worker who has had the girl under her care. In fairness to the prisoner, great efforts are made to get a complete picture of her upbringing and career, not only with a view to accurate diagnosis but also to determine whether institutional treatment is necessary. Particular attention is paid to any allegation that she has held good employment or has lived steadily and peaceably under certain conditions. The principle applied throughout is that certification under the Mental Deficiency Acts is as grave a matter for both patient and doctor as certification under the Lunacy Acts; both result in deprivation of liberty, and the reasons for such a step ought to be carefully established.

---

* Read before the Medico-Legal Society on Oct. 23rd.

A Five Years' Review of Defective Delinquents.

In the five years under review, 78 notifications of alleged defective women were received from the London magistrates and from the women's prison. Of these, 20 were considered by the prison doctor and the Council's certifying officers to be not defective, while 58 were deemed certifiable. If this average of 11·6 cases per annum in a population of over four million seems extremely low, there is reason to believe that the cause is to be found in the careful ascertainment and preventive supervision of defectives in the London area rather than in any lack of zeal in searching out defective criminals. It should also be noted that the Acts do not cover all mental abnormalities but only those coming within a certain definition. The number of weak-minded and eccentric individuals who come in conflict with the law is, of course, very considerable, but they cannot yet be dealt with under any specific Act.

The *ages* of these 58 women at the time of arrest were as follows:—

Under 20	25 cases.	Under 50	2 cases.
,, 30	23 ,,	,, 60	1 case.
,, 40	6 ,,	,, 70	1 ,,

The fact that almost five-sixths of the whole were under 30 shows that the administrative drag-net is acting effectively. It is, of course, most important in the interests both of the women and of the community to put them under care before they become confirmed in criminal habits, while training may be effective and before they have formed new family obligations. As psychologists have also found in America, mental testing is far from reliable in older men and women of degraded life; these people are most suspicious and inaccessible and, even when their coöperation is secured, it is often hard to say whether poor response is due to amentia or dementia.

The *home background* of the women was investigated wherever possible by visits from a trained social worker, or by correspondence if the girl came from the country. In eight cases the girl had been reared an orphanage; 16 cases came from definitely bad (not merely poor or ignorant) homes, 29 were from apparently good homes, and information was insufficient for classification in five cases. That exactly half came from ostensibly good homes is surprising, but a little experience of more intensive work with delinquent children has taught me how much mental strife and misery may hide beneath a respectable family exterior. Lack of appreciation of a girl's innate dullness is common, and of itself often causes serious discord and revolt, even in families where other children have been reared successfully. The stories of the little group of ex-orphanage pupils suggested that more attention might be paid to the detection and after-care of defectives in some of these institutions. The large orphan societies are now making very full use of the Mental Deficiency Act for the permanent protection of their charges.

School records were carefully ascertained in every case, either from the teachers or from relatives. It was possible to group the girls into two divisions—i.e., those who were recognised as defectives in childhood by the school authorities and those who were not.

Recognised as Defective.

London girls.	Special school	10	14	21
	Industrial school	1		
	"Moral defective"	1		
	Too old to have been to special schools	2		
Country-bred girls.	Special school	2	7	
	Elementary school	5		

Not Recognised as Defective.

London girls	18	37
Country girls	19	
Attainments below St. II.	14	
Above St. II. in reading	23	

23 of the 58 had arrived in London less than one year ago.

These figures are probably the most important in this paper. Their most striking feature is the extraordinarily small number of ex-special schoo girls who get into trouble with the police. For ove 20 years London has had a steady population c between 5000 and 7000 children in its special school for mental defectives, about half of them being girl Out of the thousands of ex-pupils who must b scattered in the population only ten emerge criminals in five years. The after-care of defectiv is so thorough that I doubt if many cases who ha made police-court appearances would be missed, a the test must be considered a fair one. An interesti confirmation of this view comes from Birmingham where the after-care of ex-special school-children also very good. In 4813 cases under observation ve little delinquency could be found, though the polic court files had been searched for five years. Mo of the offences were extremely trivial.

Another group which excites comment is that 14 who had left elementary school with attainme less than those of a child of 8 (some did not ev know a letter) and yet had apparently escaped t notice of the school authorities. Whether they w the victims of foolish teachers who hoped they wo "grow out of it," or of misdirected economy wh refused to make special educational provision, not clear. They include, unfortunately, two of t *married women convicted of cruelty to their childr* whose sad plight need never had arisen if legal p visions had been utilised and preventive care had be given from school-days onwards.

OCCUPATION, PARENTAGE, AND OFFSPRING.

The previous *occupations* of the 58 women w confined to low-class domestic service, factory wo and odd jobs. Six had had no previous occupat but had lived by prostitution and pilfering. T industrial inefficiency of all the women with exception was very marked and was in some cases determining factor which brought them into the ha of the police. Such unfortunates live a "harr existence," constantly losing jobs for reasons o which they have little real control and constantly loggerheads with relatives for being unable to k work.

In view of the statement still frequently made t 50 per cent.[2] of prostitutes are feeble-minded, i important to note that only 19 of the women, includ three married women, had been promiscuous gravely immoral. An interesting confirmation of estimate was given by one of the senior proba officers of London who recently told me that " feeble-minded prostitute has practically vanished the streets of London, a very different state of aff from 30 years ago!" It should be added that th poor women seem unable to hold their own in thi in any other occupation, and their stories are pit records of exploitation and squalor. Only six them, however, had suffered from venereal diseas

The *racial aspect* of deficiency is very promin to-day, and this group of delinquent defectives mi be expected to provide sensational figures.

Offspring.—Of the 50 unmarried women nine borne children:—

6 had borne 1 child each	6
1 ,, ,, 2 children	2
2 ,, ,, 3 ,, each	6
Illegitimate	14

Of the eight married women:—

3 had borne 0 children	0
1 ,, ,, 1 child	1
1 ,, ,, 3 children	3
1 ,, ,, 4 ,,	4
1 ,, ,, 5 ,,	5
1 ,, ,, 7 ,,	7
Legitimate	20

Of the 34 children, eight were dead at the time mother was arrested. Three only of the children

---

[1] Report of the Birmingham Special School After-care S Committee. 1930.

[2] It is significant that most of these figures come from count where some form of the "maison tolerée" system is in existe A feeble-minded girl is the ideal occupant of such an establ ment—from the point of view of her employers.

known to be defective and the mentality of two more was doubtful, but information was very incomplete, as many of the children were in the care of the guardians or of relatives at a distance. Of the 32 London girls it was possible to say definitely that they had only produced two defectives among their offspring who had attained school age.

Information about *family histories* was insufficient to justify an opinion as to how many of the parents of the 58 prisoners were themselves defective. In at least 20 instances there was evidence of grave social incapacity and moral failure on the part of one or both parents, but he would be a bold diagnostician who would say that such failure in persons usually not seen and often long since dead was due to mental defect. I am aware that diagnoses of this kind are often made and are indeed the basis of much popular "eugenic" lore, but I am entirely sceptical of the value of such pedigrees. An interesting feature of this survey is the light it has thrown on the difficulty and expense of elucidating a "family history" worth the paper it is written on. Careful inquiry has not brought to notice any instance where the parent of a [illegible] defective woman was certified, and in only three instances had a sibling been certified or given sufficient evidence in his behaviour to justify a diagnosis of deficiency. The numbers dealt with are so small that the figures have little statistical value, but they are not so unusual as might be imagined.

CRIMES AND CULPABILITY.

The following table shows the *nature of the offences* with which the women were charged and the *mental age* of the culprit.

Mental Age with Relation to Nature of Offence.

Mental age ..	6	7	8	9	10	11	12	Total
Larceny	—	—	8	6	2	3	1	20
Wandering, begging	2	4	1	7	2	1	—	17
Violence to person or property	1	—	—	3	1	—	1	6
ndecency	—	—	1	2	—	—	1	4
Attempted suicide ..	1	—	—	—	—	—	3	4
Cruelty to children ..	—	1	2	—	—	—	—	3
Attempted murder..	—	—	—	—	1	—	—	1
nfanticide	—	—	—	1	—	—	—	1
Manslaughter	—	—	1	—	—	—	—	1
Murder	—	—	—	—	—	1	—	1
—	4	5	13	19	6	5	6	58

It will be noted that 32 of the 58 fall within the medium grade feeble-minded group—i.e., those who can usually "float" in the population, given good home support and suitable training, but have great difficulty in coping with any crisis on their own initiative. The table bears out the contention that the low-grade defective in London is adequately protected and is not a social danger. The few exceptions here shown are country cases or elderly women who had escaped the care of the Mental Deficiency Acts. Moreover, these imbeciles and low-grades do not contribute illegitimate children. A mental rating of 10, 11, or 12 years in formal tests would not, of course, in itself justify a diagnosis of mental deficiency. Mental tests are, however, not the only touchstone of intelligence, invaluable as they are for providing objective standards by which to compare individuals; in every case in this series the diagnosis has been subsequently confirmed. The 10- and 11-year-old groups here were undoubtedly feeble-minded, but mainly owed their superior rating to the fact that they scored unduly high on verbal tests. The 12-year-old group comprise most of those subsequently transferred to mental hospitals and one victim of encephalitis lethargica. These "12-year-old" women showed a long history of irrational, violent, and incorrigible conduct, without any reasonable motivation and not amenable to training or punishment. Certification under the Lunacy Acts had been considered and definitely rejected as wholly impossible, though it was suspected, correctly, that the mental instability would subsequently develop into a psychosis. Every effort was, of course, made to exclude any cause for their irresponsible behaviour other than innate mental abnormality.

The *culpability* of the prisoners varied very greatly, as it presumably does among their normal companions, and it had little relation to the offence with which they were charged. For example, an old woman charged with the manslaughter of her daughter by neglect proved too confused and ignorant to grasp properly the gravity of her position or even what she was supposed to have done wrong. Two of the three married women convicted of cruelty were in the same situation, and of the same type was an "attempted suicide," a little servant girl (earning 1*s.* a week and her mistress's old clothes) who had decided to end her life in Hyde Park after a domestic row but repented after licking the cork of the lysol bottle. On the other hand, some of the girls were greedy young thieves or prostitutes who definitely preferred snatching a living how they could to any effort at work. Most of them, whether vicious or merely bewildered, were of trivial importance as criminals, and required care and protection mainly for their own sake or that of their relatives. Fifteen of the 58, however, might fairly be described as pests to the community to a greater or lesser degree, while seven of these 15 constitute a group of really dangerous "moral defectives" (though only one was certified as such), each of them worthy of study if space would permit. Four had made attempts at murder and had a long history of irrational violence to persons and property, their victims being usually inoffensive relatives or persons who had befriended them. One of this group of 15 was an encephalitic, who showed very well the typical impulsive tendencies and lack of inhibition with little disturbance of intellectual powers. Four of the others gave rise to strong suspicion (subsequently confirmed by the medical superintendent under whose care they came) that their mental state was definitely psychotic. The border-line between congenital amentia and the schizophrenias is sometimes a narrow one—indeed, the underlying pathological condition may be very similar—and it is not easy to find the appropriate label. All these girls gave a history of a "difficult childhood," sullen, vindictive, irresponsive to affection, with a marked increase of instability at puberty, showing itself in violence, strong sexual or homosexual trends (sometimes in the same individual), and incapacity for settled work and a gradual "retreat from reality" into a world of phantasy. How these girls stand under any legal definition of responsibility is disputable, but it is impossible to deal with them without feeling that lack of ability to bring their actions under the control of reason is due to mental disorder, not to any deliberate fault of the will. That they need care and control for their own good and that of others is certainly beyond argument.

The following case illustrates social disaster brought about by sheer mental incompetence:—

A girl, aged 22, first came to notice when serving a sentence of three months' imprisonment for cruelty to her children, her husband having received a similar sentence. The prison officers had found that she was only capable of understanding the simplest orders and that she had to be treated like a child. She proved to be a blue-eyed, rather pleasant-looking girl, not obviously defective. She did not know a letter, but that had no significance as, like many canal children, she had never been to school. What was more unusual was that she had no idea of number, beyond possibly simple change from a shilling; she could not add 3 and 3. She did not know how long she had been married, or the ages of her children, or when or where her last baby was born! In mental tests she was barely at the 7-year level. Nominally a Catholic, she had had no religious teaching at all. The girl was frank and friendly, and anxious to tell her troubles. She had genuinely no idea why she had been put in prison. "I hadn't no money for milk and I fed it on sop and it cried a lot—and a policeman came and took me away." To all appearance she really loved her babies, and she questioned me eagerly as to when she could go back to them.

On inquiry it was found that her mother was a woman of at least average intelligence who still earned her living on the barges. Her father was dead. The mother had always thought the girl dull and had not wished her to marry, but the ceremony became necessary when she was 18. After marriage things got worse, and one day, when the baby was a few months old, the mother found her daughter asleep on the towpath in the pouring rain with the infant beside her. Since then she had taken entire charge of that child, but two younger ones had arrived, and the squalor and misery of the barge household became a scandal in that clean-living community. The husband, too, found life intolerable and knocked her about. At last the unspeakable condition of the children compelled the neighbours to intervene. They called in the National Society for the Prevention of Cruelty to Children, who found the child of 2 unable to sit up, and the baby a "skeleton"; both children are thought to be defective, but that is not yet certain.

There was no trouble in dealing with this case under Section 9, but, unfortunately, she proved to be again pregnant. After a brief stay in a convent home she was transferred to the care of the county authorities of her place of residence. The children were taken by the guardians. The husband, who at first said he had no further use for her, now vaguely says he thinks he would like her home, though he knows she could never keep a home for him.

The next case is at the other extreme of intelligence, and shows an example of the strange conduct-aberrations included in the "moral defective" group.

A girl, aged 16½, second of five sisters, was charged with uttering threats to her eldest sister. The first attempt to examine her failed, as she was having prolonged bouts of hysterical screaming. At the second interview she proved to be an attractive, pleasant-looking child who, without asking my name or business, confided her closest secrets at interminable length. The standardised tests, in which she coöperated well, showed her mental age to be nearly 12. Her memory was excellent, her response quick, her concentration good. Her main characteristic was a passionate father fixation, the most intense and overt example I have encountered. She had been his pet up to his death (he had been killed on active service) when she was 7 or 8, and she was encouraged by him to hit the other little girls with impunity. If her mother attempted to control her, the father would knock her down in front of the children. She remained throughout childhood violent-tempered, aggressive, passionately attached to her father's memory, and bitterly hostile to her mother and to the unfortunate elder sister. She admitted to me freely that she had never had anything but kindness from these two, who are amiable and affectionate characters, and the real nature of her feelings towards them remains obscure. At the age of 13 her mother's second marriage brought about a crisis of jealousy; she flung a knife at her and otherwise behaved so outrageously that the mother was obliged to charge her, and the child was put on probation for two years. Under the care of a sympathetic probation officer efforts were made to place her in four homes and four private families, but she had invariably to be removed as violent, quarrelsome, and insubordinate, though capable of good work and very attractive when she liked. Finally, she could not be placed further, and at 16 she was sent home, only to find that the still-hated elder sister had just become engaged. Her own tendencies were homosexual, and she resented this marriage intensely. She behaved so violently that the family were "afraid to go to bed" on one or two nights; she burnt a 10-year old sister's leg with a poker on some trivial provocation, she threw a knife at another sister, and a loaf of bread at her mother who was ill in bed, and she pursued the wretched elder sister with such abuse and threats that the police had to be called in. Even in the police station and in prison she repeated her threats with incredible cold-blooded malice. I pointed out to her that people who killed others were hanged for murder, and this evidently made some impression, for she told a visitor some days later: "I would like to bash my sister's head so that she died *slowly*, and then I wouldn't be a murderer!" She could give me no reason for these amiable sentiments except that the sister was the eldest child, and her mother had given her the father's war medals. She was, I found, truthful, except for a few bombastic lies based on the father complex.

The girl was not amenable to ordinary prison discipline, and, indeed, it was doubtful what purpose such punishment would have served. She was certified as a "moral defective," but it was thought that the condition was at base a psychosis of the dementia præcox type, and this diagnosis was confirmed by the superintendent of the institution to which she was sent. Her conduct improves, but she remains inaccessible to mental treatment, and the prognosis is not good.

The Care of Defective Delinquents.

The disposal of the women certified is, of course, at the discretion of the learned magistrate, who almost invariably, however, accepts the suggestions of the Council's representatives. Some magistrates are still not wholly alive to the preventive value of the Mental Deficiency Acts, and the importance of getting a case under supervision in her own home when institutiona care does not seem to be called for. Ordinary probation is not usually a success with defectives, and the cast an unfair burden on overworked probatio officers.

Still in M.D. institutions	24	

It is an old gibe against the Mental Deficiency Act that they make it possible for a man "to be sent prison for life for stealing turnips." If the man theft of the turnip was due to starvation, and investi gation showed that his mental incapacity disqualif him from earning his living, it might well be prolonged—even lifelong—institutional care was th kindest way of dealing with him. The magistr very wisely consider need for special care and rather than the actual offence for which the defect came before the court. In the great majority of in this series the girls either had no family or th relatives—very excusably—expressed themselves " the end of their tether" and unable to take th responsibility. It is the best parents who are anxious for institutional care if their children are serious trouble. *One rule of primary importance* not universally appreciated. *Defectives who h* shown any sign of giving trouble should never put under the sole care of a parent of the opposite To this rule there is no exception, and we have ma instances of the deplorable effects of ignoring it sentimental grounds.

The small number of women placed on prob might be disappointing if one did not recall that th for whom such treatment would be suitable mostly dealt with under preventive schemes defectives and never reach the courts. In view of youth of the prisoners at the time of arrest, it reasonably be hoped that several more will st and eventually be returned to community li Fortunately, the training offered by the colonies which the women are sent (especially the St institution for violent and dangerous defectives progressive and aims at developing latent capaci and virtues, even in the apparently hopeless.

Sterilisation.

As an immediate treatment for delinq sterilisation is *ipso facto* excluded, as obviously does nothing to improve the antisocial behavi which has brought the defective into conflict the law. In the neat American phrase: " offences against the community are not limited reproduction," and often do not include any tenden towards it. Contrary to the belief of some magistrat cutting the Fallopian tubes or vas deferens is not cure for hand-bag snatching. Among those who w ranked as delinquent defectives in my series were squalidly promiscuous, the homosexual, suffer from venereal disease, the suicidal, and the poten murderer. None of these persons could be sterili and turned loose, and it would be grossly unfair extravagant to subject a person to the risk of abdominal section if she is to be indefinitely segregat Sterilisation would not cure the mental incompeten which was at the root of the troubles of other ca is not, I think, appreciated that sterilisation is not w used in the United States as a punishment[3] for linquents of any kind.

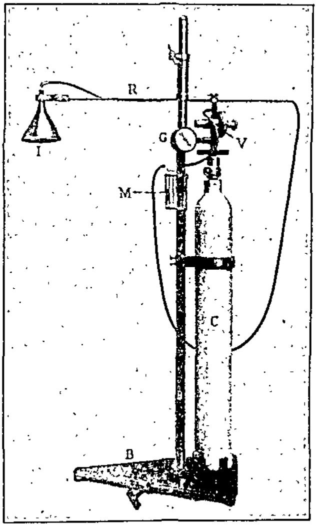
As a preventive measure sterilisation is even more practicable. It *obviously cannot be used for* whose defect is never ascertained, as was e case with many of these women, nor could it be ntemplated that local authorities would have the rontery to sterilise a child leaving school to whom ey had not offered a special education appropriate his needs. Only rarely does moral deficiency a fixed condition declare itself in childhood, and if e leavers from special schools were to be sterilised iolesale, thousands would have to be mutilated in der to catch the few dozen who become delinquent the few hundred who bear children. The effect of rning hordes of sterilised adolescents loose in the mmunity *requires further consideration before the periment is tried.* Most *important* of *all,* no parent uld be persuaded to allow a high-grade 7- or year-old child to enter a special school if sterilisation re to be her fate on leaving—or even if a shadow the possibility of such a fate hung over her. There no question that the special education of defectives, ch is the best preventive of crime, would be most ively interfered with.

In California the sterilised woman does not cease be an expense to the community, but is most refully supervised by trained social workers. She kept on a string (even if married!) and is hauled ck to the institution at the slightest sign of irregular nduct.[4] That is to say, the only benefit that sterilition could secure is: 1. To prevent the birth of such ildren as might be conceived before the woman's egular conduct attracted attention. 2. To enable a man to marry, without the husband being necesily aware she had been sterilised. Whether the ulcation of such a philosophy of marriage into the pulation is likely to raise ideals of family life is other matter. 3. To prevent the birth of more ldren, as in the case of the one married woman in this ies returned to her family. These are literally the y cases to which sterilisation can be applied in the e of the mentally defective, and the result is surely *idiculus mus* to emerge from such a mountain of paganda! A final question which occurs to me h the picture of high-grade patients fresh in mind his: if they improved sufficiently in conduct to der life in the community socially possible, how ld it be subsequently demonstrated to a judge and y that they were—or ever had been—mentally icient, and what would be the fate of the doctor o had sterilised them or secured their sterilisation his certificate?

This brief survey of a group of defectives in the unty of London is presented with all the diffidence uced by a knowledge that among a great popula-n many defectives may be missed. It may, however, ve a useful purpose in getting the subject into us and into a true relationship with the study of inquency among *normal persons. It may* also gest that a frontal attack upon the defective *qua* inquent is only a very small part of the intelligent dling of the problem of mental deficiency. Early ognition and preventive supervision and training the best methods of ensuring that subnormal sons shall be assimilated into the life of the comnity or, if that is impossible, put under conditions piest for themselves and others.

PORTABLE APPARATUS FOR OXYGEN.

Dr. Lachlan Grant writes: In the vicinity of sent-day hydro-electric power schemes it is essary always to be prepared for the immediate ninistration of oxygen to cases of severe shock. G. B. Brook, F.I.C., chief chemist to The British minium Coy., Kinlochleven, after lending out a keshift apparatus on several occasions, has designed the simple combination shown in the photograph. The oxygen cylinder is easily removed and replaced, although when in position it is held securely. Controls and gauges are in convenient positions and the glass *manometer is protected by a small but strong metal* cage. The rubber tubing to the vulcanite mouthpiece is threaded through a small metal tube, which is adjustable both vertically and horizontally. The centre of gravity is adjusted so that the apparatus will not topple over, and the base runs silently on three ball castors, so that it may be brought up alongside the patient or bedside with the greatest ease. When once assembled it can be kept so, and wheeled or lifted about quite handily—e.g., into a car, and can be very easily transported to any part of a country practice.



Portable apparatus for administration of oxygen. R = rod adjustable vertically or horizontally. I = vulcanite inhaler. V = regulating valve. G = pressure gauge. M = indicating manometer, protected by grid. C = cylinder (20 cubic feet). B = base on ball castors.

The entire apparatus can be made up for a few pounds, and the cost of maintenance is almost negligible. Mr. Brook will be pleased to answer any inquiries.

ANTIVIRUS AFTER MASTOID OPERATIONS.

ALTHOUGH recovery after the mastoid operation is nearly always straightforward the patient is, nevertheless, susceptible for the first seven or eight days to complications due to extension of the infective process to the lateral sinus or meninges. With a view to minimising this danger, Dr. H. Grain[1] has made use of Besredka's antivirus[2] applied frequently to the wound, and claims that this is a powerful aid to treatment. He employs a solution prepared from streptococci, staphylococci, *M. catarrhalis*, pneumococci, pneumobacilli, and *B. pyocyaneus*, and his technique *is as follows.* At the end of the operation a drainage-tube of small calibre is placed at the bottom of the cavity, passing from the level of the antrum to emerge from the lower angle of the wound, and is covered by a packing

[4] Gosney and Popenoe. Op. cit.

[1] Presse Méd., Dec. 10th, 1930, p. 1681.

[2] See THE LANCET, 1927, ii., 73; 1929, i., 1092 and 1157.

of ribbon gauze soaked with the vaccine; above this is placed another tube twice the calibre of the first, perforated with several holes near the end, and long enough to emerge through the upper angle of the wound and to pass above the bandage; superficial to this is a second layer of ribbon gauze, also impregnated with the antivirus, outside which the usual dressings are applied. Ten to twenty cubic centimetres of the antivirus are introduced through the larger tube three times a day for the first two days, and afterwards twice a day. The outer dressings are changed every other day, but the packing is not disturbed until the sixth or seventh day; every half hour for two hours before this dressing 10 c.cm. of hydrogen peroxide is instilled through the long tube to facilitate removal of the packing. If the wound is healthy the irrigation tube is now removed, but the drainage-tube is replaced and the cavity packed with vaselined gauze; if the wound does not appear quite satisfactory, the treatment with antivirus is continued for a further 24 or 48 hours. Dr. Grain appears to have used this method for a large number of patients with satisfactory results, but says that in a few cases it has given no result. He thinks these failures are due to the causative organism being absent from the stock antivirus—e.g., *Streptococcus hæmolyticus* or *mucosus*, or "other atypical microbe"—and he finds local treatment with an autogenous preparation is successful in such cases. It might be objected that complications, such as sinus thrombosis and meningitis, are extremely rare after the mastoid operation in cases which have shown no suspicious symptoms beforehand and that it is precisely in those due to hæmolytic streptococci and to the *S. mucosus* that such sequelæ are commonest.

NEW PREPARATIONS.

PSYLLA (psyllium seed); LACTO-DEXTRIN (Battle Creek Food Company, Mich., U.S.A. Distributing Agents, Coates and Cooper, 41, Great Tower-street, London).—This company have sent us specimens of their laxative agent, Psylla, and their preparation, Lacto-Dextrin, for use in intestinal toxæmia. Psyllium seeds when immersed in water yield a mucilaginous substance which is able to take up relatively large quantities of water to form a gelatinous mass. They become in this way a useful lubricant, while the emollient character of the mass renders it of special service in fissure or hæmorrhoids. The same firm has received favourable reports from the clinical use of their combination of lactose and dextrin.

PEPTALAC; COW AND GATE RUSKS (Cow and Gate, Ltd., Guildford).—Peptalac is pancreatinised milk food predigested by a special process which assists assimilation. The predigestion of food by enzymes is no novelty, but the particular claim for Peptalac is that, with care and the use of a thermometer, a valuable beverage ready for use can be promptly obtained with the medium of hot water. The difficulty of the addition of raw cow's milk of varying composition to foods is thus avoided, as well as the more elaborate processes of preparation entailed by reheating and cooling. At the same time the firm send us a specimen of their Cow and Gate Rusks, which are deservedly well known.

RELAPSING FEVER IN TEXAS.

RELAPSING or African tick fever has not often been seen in the United States, though there was an epidemic in New York and Philadelphia in 1869, and five cases have been reported from Colorado within more recent times. A report of a cave infested with infected ticks now comes from Central Texas.[1] The cave was first explored by four youths who noticed on emerging therefrom that several small ticks were sticking to their legs. These they easily removed, but six days later the boys were all stricken with a fever which rapidly mounted to 103° or 104° F. Other symptoms were malaise, headache, leg-ache, and a persistent sense of chilliness with nausea and After these symptoms had continued for four days. macular rash appeared, and a few hours later th temperature began to decline to the accompanim of drenching sweats. The first relapse occurred i four to five days and showed the same symptoms, b was less severe and without any rash. The secon afebrile period lasted from four to seven days, and wa followed by a third period of fever during whi actively motile spirochætes were found in the bloo Intravenous doses of neoarsphenamine from 0·4 upwards were necessary to cure these patien Dr. Graham, investigating the cave in which patients had acquired the infection, became infect himself. The sand on the floor of the cave was fou to contain as many as 30 or 40 ticks per handf These were identified as *Ornithodorus turicata*. In tion of three rabbits with tick juice resulted in t speedy death of two, and in violent and fatal illn for the third after six days' interval. Typical spi chætes were from 18 to 25 microns in length, havi from 10 to 15 spirals.

STARK INDIA.[1]

As editor of the *Civil and Military Gazette of In* Mr. Trevor Pinch saw many things which do often come to the notice of a casual visitor, and us vivid glimpses of Indian life and customs. account of the flagellations in a Mohurrum proc and the disastrous Hindu pilgrimage of 1928, particular, are arresting. A considerable part of book has a medical interest, and generous tribut paid to the work of the Indian Medical Ser Perhaps undue stress has been laid on the sex ques prominent as that indubitably is in Indian In the section of the book concerned with sex s of the views advanced must be taken with especially the inference drawn from the story of beautiful Eurasian girl. That story was curren up-country clubs 30 years ago, and was not t very seriously.

Corrigendum.—On p. 30 of our last issue refer was made to a short survey of "Psychopathol published by Messrs. Baillière, Tindall and Cox. author's name is Dr. J. Ernest Nicole and no stated. We regret the error.

Births, Marriages, and Death

BIRTHS.

CLAXTON.—On Dec. 31st, 1930, at a nursing home, San the wife of Dr. E. E. Claxton, Folkestone, of a son.

ADDRESSES AND ORIGINAL ARTICLES

NEPHROSIS.*

By T. Izod Bennett, M.D., F.R.C.P. Lond.,
PHYSICIAN TO OUT-PATIENTS, MIDDLESEX HOSPITAL, AND PHYSICIAN TO THE ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.

IMMEDIATELY after the war the attention of medical men in this country interested in nephritis was directed to publications by Albert Epstein of New York,[1] describing a group of cases of nephritis with œdema in which he had found the prognosis to be good, and in which he claimed that cure of the œdema could be brought about by the employment of diets abundant in protein together with the administration of thyroid extract. At much the same time there ippeared work by a number of German observers f whom Munk,[2] Volhard, and Fahr[3] were the incipal. This emphasised the importance of a group of cases usually included amongst those labelled is Bright's disease, but in which the histological esions were confined to the tubules, and were purely legenerative in character. To these cases the name nephrosis," originally suggested by Müller,[4] was iven.

As time has gone on Epstein and his followers in merica, and others elsewhere who have become nterested in these cases, have adopted the word nephrosis," with variations such as lipoid nephrosis, hronic nephrosis, or essential nephrosis, to include he cases indicated above. Much confusion has nsued because more common examples of Bright's isease characterised by œdema in conjunction with ised blood pressure and nitrogen retention have been ferred to as "nephritis of nephrotic type" or by milar terms, and at the same time many pathologists ave taken exception to any classification which nplies that degeneration is anything other than the rst stage of ordinary inflammation.

To-day, this confusion is tending to disappear, nd it is becoming recognised that a group of cases oes exist according closely with the original views the American and German workers. It is, however, ery important to define with exactitude the points hich permit of any case being included under this ead. Certain clinical, biochemical, and pathological atures must be present, and certain others must finitely be absent. These are included in the llowing table, in which the positive and the negative dings are clearly separated.

Characteristics of Nephrosis.

	Positive.	*Negative.*
nical ..	Albuminuria + + +. Œdema (lipoids in urine + –).	Normal blood pressure and heart. Normal retinæ. No hæmaturia. No epithelial casts.
ochemical ..	Increased blood cholesterol. Diminished plasma proteins. Reduced basal metabolic rate.	Blood-urea, chlorides, &c., normal.
thological ..	Degeneration of renal tubules (lipoid infiltration).	Normal glomerul and vessels.

Considering the general features indicated by this ble, it is clear that the most important points are: 1) that the case must exhibit œdema and albuminuria, and (2) that there must be no evidence whatsoever of involvement of the cardiovascular system.

About a year ago a closely reasoned paper was published by Christian,[5] who called attention to the extreme rarity of post-mortem records supporting the conception of "nephrosis." He was able to collect only about 20 cases from the world's medical literature, and the general trend of his review was to throw considerable doubt on the existence of the disease as a separate entity. Some of the American supporters of the conception have explained the rarity of post-mortem material by suggesting that the disease is so benign that complete recovery is usual, but with such a view I cannot personally agree, since in my experience complete recovery is very rare.

At the time when Christian's review was published, a case typical of nephrosis was under my care in the Middlesex Hospital, and within six months I was able to follow a further case almost from the start of the disease until its fatal termination. The full details of these cases are being published, and it is noteworthy that during the last 12 months details of about 15 other cases have appeared in print in the world's literature, the most recent being those of Van Slyke and others.[6]

A Typical Case.

The following is a brief description of a case recently under my care:—

A man, aged 35, came to me for advice concerning swelling of his legs accompanied by albuminuria. Pitting œdema was present in both legs to just below the knees. The urine became almost solid on boiling, but otherwise no abnormal feature of any sort could be discovered. The optic fundus, the heart, the blood pressure, were all quite normal. Blood analysis gave normal figures for urea and non-protein nitrogen, calcium, phosphorus, &c., but the cholesterol stood as high as 300 mg. per 100 c.cm. and the plasma-proteins were reduced, the reduction being greatest in the serum albumin.

Close inquiry into the past history revealed no serious illness of any sort. The Wassermann reaction was negative. Swelling of the ankles had been noticed periodically for a few weeks on several occasions during the previous twelve months and had been continuously present for two months before I first saw him.

After he came under my observation he remained at work and reported to me at hospital twice weekly for many months bringing with him on most occasions a suitcase containing all the urine passed for 48 hours. In this way we were able to estimate the amount of albumin he was losing, and this amounted on the average to 15–20 g. per diem. It has not always been sufficiently realised how enormous is the total of albumin lost by these patients. The white of one egg contains approximately 6 g. and it is clear that a patient such as the one at present described may lose the equivalent to 5, 7, or even 12 whites of egg daily. Such a loss must before long exercise a profound effect on the circulating blood.

The patient was encouraged to take full amounts of protein in his food, particularly the vegetable proteins such as have been advocated by Epstein. His diet was kept as free of salt as possible, and he was given increasing doses of thyroid extract until he was taking grs. 60 daily; an increasing pulse-rate prevented the dose being pushed higher than this. In spite of this treatment œdema steadily increased, and before long the scrotum and penis and abdominal wall were involved, ascites was present, and there were physical signs of double hydrothorax. The patient was still at work but had put on 3 st. in weight, and was in such a condition that when he had been seated at his desk for a few hours he was obliged to massage his legs before he could straighten his knees.

He was then admitted to hospital. His condition was the same, there still being no change in the blood pressure and the blood chemistry remaining normal except for hypercholesterolæmia, and marked lowering of the plasma-proteins. He was given a series of intravenous injections of salyrgan, but even full doses of this drug did not increase the output of urine, which remained in the region of 600 to 800 c.cm. daily. After being in hospital about 14 days, he developed pain in the abdomen, the temperature rose, he became delirious, the abdominal wall showed discoloration, and in 48 hours he was dead from a pneumococcal infection of his œdematous tissues.

---

* A lecture delivered before the Fellowship of Medicine in vember, 1930.

The post-mortem examination revealed a heart of normal size, and kidneys somewhat enlarged by œdema, which on microscopic section showed lesions of a degenerative nature and confined to the tubules. The glomeruli appeared perfect.

Such is a classical example of "nephrosis." It may be asked why I have not used the term "lipoid nephrosis," nor alluded with more emphasis to this aspect of such cases. Cholesterol is almost always present in excess in the blood of these patients, but it is also present in the blood of many cases of nephritis exhibiting both œdema and cardiovascular change. It is not a feature of nephrosis alone, as far as we know; the observations of Maxwell[7] and of Gainsborough[8] seem to bring this out clearly. The "myelin" kidney, described by Kaiserling and Orgler,[9] McNee,[10] and others, is a greasy kidney loaded with lipoids, but is not necessarily from a case of nephrosis; it may be recovered from other types of nephritis, always with œdema, but sometimes with cardiovascular and marked glomerular change. Too much emphasis should not therefore be laid on this aspect, although it is an important feature of the biochemistry.

Ætiology and Prognosis.

The case which has been described is typical of many which have been recorded in the literature; but it should be noted that in many others some important ætiological factor can be traced. Thus, the cases originally described by Müller and Munk were nearly all of syphilitic origin, and it is common knowledge that in the days when syphilis was prevalent, many cases of intense albuminuria and œdema were observed which recovered complete health under treatment of the specific infection. Other cases of nephrosis appear to be of tuberculous origin, and amyloid disease appears to be essentially similar in many of its features. When this has been said, there remains at present nothing further to tell concerning the ætiology of this condition, and in many, perhaps the majority, of all the cases no ætiological factor of any kind is at present discoverable. Perhaps the most important negative fact to remember being that a history of severe scarlet fever or of recurrent tonsillitis always makes it probable that a case belongs to the category of glomerulo-tubal nephritis rather than nephrosis.

As regards prognosis, it would seem that the optimism of the German and American observers, which is evident in the first descriptions of nephrosis, is not justified by the experience of their successors. A proportion of cases in childhood appear to make complete recovery, but unless an ætiological factor, such as syphilis, is discovered and removed, one must remain doubtful as to permanent cure for a very long time indeed.

Importance of Nephrosis.

It may be asked why, if these cases are rare, they are so important. In the first place they are probably much commoner than is usually supposed; many pathologists say that they have never seen an example, the paper by Christian, to which reference has already been made, suggests an almost extreme rarity, and yet in the last 12 months the number of recorded cases has increased by over 50 per cent. Further, we must acknowledge that in the experience of many people, cases conforming clinically to this description are known to recover in a certain proportion and so escape observation by pathologists. We cannot therefore dismiss the group merely on the grounds of rarity.

But apart from this they have great importance a indicating a definite subdivision in the classification of Bright's disease. That great medical [illegible] in his "Reports of Medical Cases," focused the attention of the world on the association between dropsy, disease of the kidneys, and albuminous urine. He called attention to cases with great renal degeneration and to others with granulation of the kidneys, but although he distinguished three main types, he clearly stated that he was unable to decide whether these represented different diseases or stages of the same malady. In the epoch following Bright, an endeavour was made to distinguish two main types termed respectively "parenchymatous" and "interstitial" nephritis. These words remain too frequently in the nomenclature, for it is common knowledge that it is exceedingly difficult histologically to demonstrate a case with pure parenchymatous inflammation and no interstitial lesions, whilst in cases of so-called interstitial nephritis there is always considerable change in the epithelium of the organ.

A great advance was made during the nineteenth century when Gull and Sutton[11] separated off group which they called "arterio-capillary fibrosis"; this is the group which is becoming known to-day as ischæmic nephritis, and is recognised as a late result of primary hypertension, the sclerosis of the kidney being secondary to vascular changes. It generally agreed that in such cases death is far more often the result of cerebral hæmorrhage or cardiac failure than of renal failure.

But even with the recognition of the ischæmic or arterio-sclerotic group as a separate entity, there remained a heterogeneous group of cases classed Bright's disease, in which clear separation in parenchymatous and interstitial subdivisions was n possible, either clinically or pathologically.

The next attempt at classification arose from brilliant investigations of Widal and his school France, who revived interest in the blood chemistry and drew attention to the importance of nitrogenous constituents of the blood as affording index of approaching uræmia. Widal[12] endeavoured to set up a "functional" classification of nephritis dividing cases into those in which nitrogen-retention was conspicuous, and those in which he believed retention of chlorides to be the outstanding feature with œdema as a consequence. This classification has not stood the test of critical inquiry. It perfectly true to-day to say that, in cases of re disease with œdema, chloride taken by mouth te to make the œdema increase, but we know that t is not due to any impermeability of the kidney salt, but is rather the effect of a "pre-renal deviation of water and crystalloids from the blood plasma i the tissue spaces. A similar phenomenon occurs cardiac œdema, and therefore we are unable to support to the hypothesis that there is a variety of renal damage in which the excretion of chlorides is prevented in a manner analogous to the failure urea excretion in cases of renal sclerosis.

Subdivisions of Bright's Disease.

The classification of nephritis which appears tena to-day is that which recognises an *acute glo inflammation* as the initial lesion in the vast majo of cases. We recognise acute nephritis as a di which essentially damages the glomeruli and ch nephritis leading to secondary contraction of kidney is a late consequence of such initial in This group, which may be subdivided according as initial damage to the kidney is diffuse in type focal in character, affecting certain groups of glomeruli only, includes the forms of nephritis occurring with infectious fevers, tonsillitis, and so on.

Next we recognise the primary arterial group, first described by Gull and Sutton, usually spoken of to-day as *ischæmic nephritis;* a group in which primary hypertension is the first manifestation of disease and in which cerebral hæmorrhage or cardiac failure are far more often the cause of death than is uræmia. In such cases a sclerotic kidney is always found at autopsy, but although this shows extensive destruction of the organs on microscopic examination, t is unusual for such destruction to have progressed sufficiently to cause death before either the rupture of a cerebral blood-vessel or failure of the heart muscle has interrupted the life of the patient.

And now we have *nephrosis* as a third member in the group constituting Bright's disease. I have already indicated its characteristics, and it is essentially he fact that the primary lesion is a degeneration of he tubules which enables us to put it forward as a parate entity.

The Production of Œdema.

But there is a further reason which makes the ecognition of nephrosis important—namely, the ght which this conception throws on the mechanism f œdema.

Admitting that glomerular nephritis is often sponsible for œdema, it is nevertheless a fact that ses of nephrosis exhibit the so-called "renal" dema in its most uncomplicated form. In nephrosis e known lesions are relatively simple, being ractically confined to the renal tubules. The ymptoms are few, being merely albuminuria and dema, and the blood chemistry exhibits no changes ve an excess of cholesterol and reduction of the asma-proteins. Accepting these facts, it becomes obable that the œdema of these cases is the direct sult of the loss of protein from the blood plasma hich follows the intense and prolonged albuminuria.

Generalised œdema, such as we see in the medical ards of our hospitals, is the result of passage of ter and salts through the capillary walls into the sue spaces. In such cases increased permeability the capillary wall may sometimes be present, but en if this factor is important, it is necessary for rtain forces to be in action in order to bring about e passage of fluid into the tissue spaces. These ces are many and complicated, but two of them are outstanding importance—namely, the capillary ood pressure and the colloid osmotic pressure of the sma-proteins. Of these forces the capillary blood essure depends to some extent on the general blood essure, but only to a limited degree because the pillary blood pressure is constantly controlled by a vasomotor system. Capillary blood pressure is, the other hand, liable to considerable variations rough changes in pressure on the venous side. hen cardiac failure or any other cause prevents the dy emptying of the veins, capillary pressure will considerably increased, and in such circumstances see œdema of the "cardiac" or "obstructive" pe.

Turning to the second great force, the colloid motic pressure, it has been recognised since the neer work of Starling[13] that the molecules of otein in the plasma exercise a continuous osmotic ce, tending to retain water and salts in the circulat- blood. Fibrinogen has little power in this respect, bulin has more power, but it is essentially the umin which exercises the greatest osmotic force. has been calculated by Govaerts[14] and others, who have specially studied this side of biochemistry, that the albumin molecule exercises a colloid osmotic pressure six times as great as that of globulin. It is essentially this colloid osmotic pressure which is responsible for holding back water during the passage of the blood through the capillaries and for reabsorbing water from the tissue spaces when transudation has occurred. From this it follows that if for any reason the plasma-proteins are greatly decreased, the reabsorption of water will be impeded and the production of œdema notably facilitated, and this is what happens in the so-called renal œdema. The loss of albumin through the kidney into the urine is so great that we find the plasma-proteins diminished from their normal figure of about 8 g. per 100 c.cm. to 6, 5, or even 4 g. or less, and the diminution being chiefly at the expense of the albumin, there is a correspondingly enormous fall in the colloid osmotic pressure. This is the probable explanation of "renal" œdema and such observation of the concentration of plasma-proteins is an extremely important one in biochemistry and in clinical medicine which has been all too often neglected.

Recently, in conjunction with Dodds and Robertson,[15] I have been able to investigate a number of cases of œdema of obscure origin, and we have been interested to find that in many of them there is a notable lowering of the plasma-proteins. The cases we have so far investigated have chiefly belonged to two groups. In the first group there has been cirrhosis of the liver with the collection of large quantities of albuminous fluid in the peritoneum, but in addition there has been œdema of the arms and legs, and we believe that it is the loss of albumin from the blood into the peritoneum which has depleted the plasma-proteins to such an extent that a generalised œdema has followed. The second group has consisted of cases with extensive simple or malignant ulceration of the stomach, and in these again a generalised œdema with demonstrable lowering of the plasma-proteins has been due, according to our conception, to an initial loss of albumin from the blood, so lowering the colloid osmotic pressure that œdema has resulted.

These observations have but an indirect application to the subject of nephrosis, but the application is important because it has been suggested in some quarters that nephrosis is not a renal disease at all, but is a disorder of metabolism in which the albumin molecule of the blood plasma is so changed that it can escape through a normal kidney. It has further been suggested that such degenerative changes as are observed in the kidney are merely the result of a depleted blood plasma. Our observations on cases in which the blood plasma was lowered by loss of albumin into the peritoneum or alimentary canal show that in such cases no renal lesion became demonstrable, and it therefore seems that in nephrosis it is more logical to accept the microscopic changes in the kidney as evidence of damage which allows the escape of serum-albumin as a consequence.

These observations on the plasma-proteins have yet a further application because they indicate the unsatisfactory nature of the majority of forms of treatment at present adopted. It is clear that to promote diuresis is not by itself an action tending to cure because the mere extraction of water from the tissues will leave the blood plasma as poor in proteins as before, and the only form of treatment which can be expected to cure is one which will prevent further leakage through the kidney, and restore the blood proteins to their normal condition. Diet is, therefore, very important, and even if our present knowledge is insufficient to enable us to promote the creation of serum-albumin with any certainty, it is at least logical to keep these patients on a diet containing abundant protein which will supply them with the elements necessary to combat the constant loss of albumin which is the essential mechanism of their œdema.

HISTOLOGY OF BUCCAL CARCINOMA

IN RELATION TO PROGNOSIS AND RADIO-SENSITIVITY.*

BY RALPH PHILLIPS, M.S. LOND.,

DEMONSTRATOR OF ANATOMY, ST. BARTHOLOMEW'S HOSPITAL.

THE treatment of malignant disease by radium has given a fresh impetus to the histological study of cancer, for many pathologists consider that the explanation of radio-sensitivity and radio-resistance is to be found in the histology of the cancer cell. Ewing[1] states that "the cure of carcinoma by radiation results from a nice adjustment between injury to tumour cells, ensuring their partial or complete necrosis, and injury to surrounding tissues, eliciting a reactive reparative inflammation which removes tumour debris and often destroys viable tumour cells." It can hardly be possible to obtain such a "nice adjustment" between radiation, cancer cell, and stroma reaction in the absence of a knowledge of the histology of each particular cancer under treatment. The present paper, therefore, is an attempt to find a histological explanation of the fact that local healing of carcinoma of the tongue is obtained in less than half the cases treated by irradiation. In order to have a firm background for such work it was first necessary to prove a relationship between the histology of buccal cancer and its clinical course.

If it be possible to classify with some constancy the degree of histological differentiation in a carcinoma, then it might perhaps be expected that such a classification would be correlated with events such as (1) the rate of growth of the tumour, (2) the duration of life from the detection of the growth, (3) the tendency to dissemination, (4) the time of appearance of metastases, (5) the results of operative treatment, and (6) the reaction to radiotherapy.

The life-history of a cell, like that of the whole organism, consists of reproduction (mitotic division), differentiation (changes in structure), and specialisation (development of function). It is a well-recognised biological law that there is an inverse relationsh between the processes of differentiation and speciali tion on the one hand, and the powers of reproductio on the other. Thus a carcinoma, increasing b geometrical progression without differentiation, wi grow faster and be more malignant than one in whic the cells undergo some degree of differentiation, wi corresponding diminution in reproductive activit The process of differentiation is a self-imposed bra (Broders[2]), and malignancy is dependent upon th relationship between the rate of growth and the degr of differentiation (MacCarty[3]).

Hansemann,[4] in 1893, first pointed out the relatio of the histology of a cancer to its biology, and intr duced the term "anaplasia" to describe the ve cellular, embryonic type of growth; he thought al that the histology of a cancer was of more importan in its prognosis than any other single factor. The ideas of differentiation and anaplasia have be steadily developed by many pathologists, and we finally expressed in statistical terms by MacCarty a by Broders.[5] Broders's histological classification an epithelioma depends upon the degree of differen tion it shows towards a normal squamous epitheliu The normal differentiation of a stratified squamo epithelium is from the cuboidal basal cells, throu the polyhedral prickle cells and flat squamous ce to keratinised cells; these last die to form the surf of amorphous keratin. So Broders describes Grade 1 epithelioma as being from 75 per cent. 100 per cent. differentiated, and 0 per cent. to 25 cent. "dedifferentiated"; Grade 2 is 50 to 75 p cent. differentiated, and 25 to 50 per cent. dediffer tiated; Grade 3 is 25 to 50 per cent. differentiat and 50 to 75 per cent. dedifferentiated; and Grad is 0 to 25 per cent. differentiated, and 75 to 100 cent. dedifferentiated.

The embryonic type of epithelioma Broders c completely "dedifferentiated," but, as Ewing[6] sa the idea of dedifferentiation is an unwarran assumption and contrary to sound biological princi *For in biological phenomena irreversibility* is outstanding feature; that an organism or a should retrace its steps and travel backwards alo the path of its life-history is difficult to believe. Th anaplasia is a term more applicable to the phys logical state and histological appearance of malign cells.

Another criticism of Broders's classification that a malignant growth is not uniform in struct throughout, and that therefore no single histolog section is of value as an index of malignancy. therefore specially investigated this point, and fo that such a contention was completely untrue, any rate for buccal carcinomata. Several grow were serial sectioned throughout, and in many sections from different parts of the growth taken; in every case uniformity of the growth found. Further, the lymph gland metastases were nearly every case *uniform in structure* with primary growth. It is, indeed, remarkable that structure of a carcinoma is so rigid that its metast reproduce not only its coarser but even its fi histological characteristics.

The Present Investigation.

The *material investigated* consists of all the cas carcinoma of the lip, tongue, floor of mouth, and palate treated in St. Bartholomew's H from the years 1921 to 1927, so that three ye least have elapsed for the estimation of results; addition, those cases treated by irradiation in years 1928 and 1929 have been studied from the point of view of healing of the primary lesion. The material comprises, therefore, a totally unselected group of cases, treated by many different surgeons; so that the correlation between the histogenesis of he carcinoma and the fate of the patient is obtained ndependently of any personal factor in treatment.

---

* Part of a Thesis approved for the Degree of Master of Surgery in the University of London.

Method of investigation.—All the available histological sections of carcinoma of the bucco-pharyngeal nucous membrane were collected and graded according o Broders's classification. The same was then done ndependently for the lymph glands where these had een removed and sectioned. Lastly, the clinical iotes of the patients were abstracted, and cases where io pathological section had been taken were included or completeness. By the courtesy of Mr. Lionel Colledge I was able to study some of Broders's own lides before starting the investigation; I may add hat I went over my first 100 slides independently a econd time six months later, and as this second ading in 97 slides was identical with the first, oders's method of classification is clearly both plicable and accurate.

Criteria of grading.—An epithelioma may consist masses of cells of embryonic type without any rangement or differentiation, with great variation the size and shape of both cells and nuclei, with any mitotic figures and large deeply staining cleoli, and abundant chromatin (Grade 4). Or its lls may resemble those of the basal layer of the rmal epithelium and show some degree of alignent, but little or no differentiation towards prickle-ll formation; there is some variation in size and ape of cells and nuclei, and a fair degree of mitotic tivity (Grade 3). Next the epithelioma may consist collections of cells arranged with a basal cell layer the periphery of each collection, differentiating to prickle cells and larger flattened squamous cells wards the centre, but without actual keratinisation the squamous cells; the cells and nuclei are more iform in size and shape, mitoses and large nucleoli e infrequent, and hyperchromatism is absent rade 2). Lastly, the growth may be almost wholly mposed of well-formed cell-nests; the stimulus differentiation has been much greater than that to production, and most of the cancer cells have killed themselves in forming epithelial pearls (Grade 1). Table I. summarises these criteria of grading, and the microphotographs further illustrate a typical example of each grade. It may be remarked that the stroma is not considered in this histological classification. The meaning of the stroma reaction is obscure, and conflicting views are held; therefore it was decided to confine the investigation (at any rate in the first place) to the malignant cell alone.

TABLE I.—*Criteria of Grading.*

Results.

The total number of patients investigated is 319; 71 treated by radiotherapy have all been followed up for one year or more to discover the effect on the primary growth. Of the remaining 248, 208 have been followed up for three years or more. The 40 untraced cases and 8 post-operative deaths (out of 286 patients operated upon =2·8 per cent.) have been excluded from the follow-up results.

HISTOLOGICAL GRADE AND PRIMARY SITE.

For the purposes of this investigation certain primary sites were defined: (1) the dorsum and sides of the tongue, anterior to the circumvallate papillæ; (2) the floor of the mouth, with the under surface of the tongue and the lower alveolus; (3) the base of the tongue—i.e., posterior to the circumvallate papillæ; (4) the tonsils, pillars of fauces, palate, and upper alveolus, but excluding the maxillary antrum; (5) the lower lip; and (6) the upper lip and mucous membrane of cheek.

From Table II. it is seen that the histological grading agrees with the usual clinical prognosis. For example, 86·7 per cent. of carcinomas of the lower lip fall into Grades 1 and 2, and growths of the lower lip are recognised clinically as being relatively favourable. On the other hand, growths of the tonsillar region are clinically of very bad prognosis, and it is seen that 60·4 per cent. of these growths fall into Grades 3 and 4.

TABLE II.—*Relation of Primary Site to Histological Grade.*

Grade	1	2	3	4
Site.	Number of cases and per cent.			
Dorsum and sides of tongue, anterior to circumvallate papillæ	19 (22·4)	35 (41·2)	24 (28·2)	7 (8·2)
Under surface of tongue, floor of mouth and lower aveolus	4 (10·0)	21 (52·5)	12 (30·0)	3 (7·5)
Base of tongue	0 —	7 (53·8)	2 (15·4)	4 (30·8)
Tonsils, pillars of fauces, palate, and upper alveolus	1 (1·7)	22 (37·9)	27 (46·6)	8 (13·8)
Lower lip	11 (36·7)	15 (50·0)	3 (10·0)	1 (3·3)
Upper lip and inside of cheek ..	1 (6·2)	9 (56·3)	5 (31·3)	1 (6·2)

DELAY BETWEEN FIRST SYMPTOM AND TREATMENT.

It is a fair assumption that the rate of growth of a cancer is the main factor determining how soon the patient seeks treatment. In Grade 1 buccal carcinomas the interval between the patient's first symptom and his seeking advice was 7·5 months; in Grade 2, 6·0 months; in Grade 3, 5·6 months; and in Grade 4, 3·2 months. There is, therefore, a direct correlation between the histological grade of a buccal carcinoma and its rate of growth.

PROGNOSIS.

Cure.—Taking all sites together, there were 50 three-year cures out of 215 cases followed (23·3 per cent.). The percentage three-year cures in each grade are as follows: Grade 1, 34·8; Grade 2, 29·3; Grade 3, 16·3; Grade 4, 5·9. There were 21 five-year cures out of 125 cases followed (17·0 per cent.). For each grade the percentage five-year cures are: Grade 1, 33·3; Grade 2, 23·7; Grade 3, 10·3; Grade 4, 0·0. Each site taken separately shows similar results to the summarised figures given above, and it is seen that a patient with a Grade 1 buccal carcinoma has a one in three chance of being cured for three or five years, while a patient with a Grade 4 growth has only a one in seventeen chance of a three-year cure, and none at all of a five-year cure. There is, therefore, a direct correlation between the histological grade of a buccal carcinoma and the prospects of its cure.

Post-operative survival.—The average post-operative life of 169 patients who were followed from operation until death (including some who died without certain evidence of recurrence of the carcinoma) was 17·2 months. In each grade the post-operative life in months was as follows: Grade 1, 25·7; Grade 2, 18·5; Grade 3, 13·8; Grade 4, 10·7. The total duration of the disease (from the first symptom to death) shows a similar relationship to the histological classification. The duration in months was as follows: Grade 1, 32·7; Grade 2, 24·1; Grade 3, 18·5; Grade 4, 14·1; average of all cases, 21·8 months. It has therefore been shown that there is a direct correlation between this histological classification of buccal epitheliomata and (1) their rate of growth, (2) their prognosis as to cure, as to post-operative length of life, and as to the total duration of the disease. Table III. summarises these figures, which are in agreement with those of Broders[5] an other workers.[7]

TABLE III.—*Relationship between Histological Classification and Clinical Course of Carcinomata of Buccal Cavity.*

Grade.	Cases.	Per cent. graded cases.	Average age.	Delay before treatment.	Fatal cases.		"Cures."	
					Post-operative life.	Total duration of disease.	Per cent. 3-year.	Per cent. 5-yea
			yrs.	mths.	mths.	mths.

2 ..	109	45·0	60·0	6·0	18·5	24·1	29·3	23·
3 ..	73	30·2	59·5	5·6	13·8	18·5	16·3	10·
4 ..	24	9·9	59·3	3·2	10·7	14·1	5·9	0
Not graded	77	—	60·1	5·4	16·6	20·0	21·6	12·
Total and average	319	—	60·0	5·7	17·2	21·8	23·3	17·

LYMPHATIC DISSEMINATION.

The uncertainty of clinical examination of t cervical lymphatic glands has prevented the findi of any correlation between the histological classific tion and the tendency to lymphatic disseminatio For of 59 cases with lymphatic metastases clinicall 22 (37·3 per cent.) were proved innocent microsco ically; and of 31 cases with no clinical metastas 16 (51·6 per cent.) contained carcinoma deposi microscopically. Lane-Claypon similarly fou glandular metastases in over half the cases of car noma mammæ in which the axillary glands we clinically not involved.

Of 48 cases available for study, the glandul metastasis was of the same histological grade as t primary growth in 39; in 5 it was of a higher gra and in 4 of a lower grade. These results agree wi those of Patey and Scarff,[8] who found the grade the axillary gland metastases to be the same as th of the primary mammary carcinoma in 86 per ce of cases.

RECURRENCES.

The average interval between operation a recurrence in 108 cases was 8·5 months, and in ea grade the interval was as follows: Grade 1, 9 Grade 2, 9·4; Grade 3, 9·2; Grade 4, 3·8 mont Since the nature and extent of the first opera have not been taken into account in these figures is perhaps not surprising that no well-marked corre tion between the histological classification and t time of recurrence has been found; but, at any r it is seen that Grade 4 growths tend to recur m rapidly.

REACTION TO IRRADIATION.

There is general agreement that the more a tis approaches an embryonic type, the greater is t radio-sensitivity (Dominici[9]), and that the maxi radio-sensitivity of the cell corresponds to the p of mitotic activity (Perthes[10]). It is therefore to expected that a histological classification of ca nomata, according to the degree of anaplasia mitotic activity, would be correlated with radio-sensitivity. Such a correlation has, in been obtained by some investigators, notably by Cutler[11] in carcinoma of the cervix uteri, and to a less extent by de Nabias and Forestier[12] in their karyokinetic index.

Table IV. compares the grade of the primary growth with its reaction to irradiation, and it is seen that there is no correlation whatever in the 71 cases investigated.

TABLE IV.—*Effect of Irradiation upon Primary Carcinoma According to its Histological Grade.*

Grade	1	2	3	4	Total and per cent.
Response of primary lesion to radiation	Number of cases and per cent.				
Healed	4 (50·0)	12 (40·0)	8 (40·0)	8 (61·5)	32 (45·1)
Improved	3 (37·5)	10 (33·3)	5 (25·0)	3 (23·1)	21 (29·6)
No effect	1 (12·5)	8 (26·7)	7 (35·0)	2 (15·4)	18 (25·3)
Totals	8	30	20	13	71
Average time of complete healing (in weeks) ..	11	10	19	8	12

If radio-sensitivity is not dependent upon the degree of anaplasia of the malignant cell, perhaps it is correlated with the nature of the stroma, as Stanford Cade[13] maintains. Table V. compares the reaction o irradiation of the primary growth with the degree f round-cell infiltration of the stroma, and again no elationship is found. It is not, of course, suggested hat round-cell infiltration comprises the whole troma reaction, but it is probably a good criterion, nd it admits of fairly accurate estimation in the issues. The histogenesis of an epithelioma, then, is orrelated with all its biological expressions except ts reaction to irradiation, but the following hypothesis vould include this also.

TABLE V.—*Response of Primary Lesion to Irradiation According to Degree of Round-celled Infiltration.*

Degree of round-celled infiltration.	Response of primary lesion to irradiation.			Total treated.	Total healed and imp. No. and per cent.
	Healed.	Improved.	No. effect.		
Dense	7	3	4	14	10 (71)
Moderate	8	11	5	24	19 (79)
Slight	11	3	5	19	14 (74)
None	6	4	4	14	10 (71)
Total	32	21	18	71	53 (75)

Action of Radium on Epithelioma.

In vivo, there is general agreement that the action f radium on the cancer cell may be direct—i.e., a ethal effect on the cancer cell—or indirect. The atter, according to Dominici[14] and Clunet,[15] comprises in the epitheliomata (1) a latent phase of 5 o 16 days; (2) a phase of monstrous evolution—welling of cell and nucleus, atypical mitosis, &c.; 3) a phase of diffuse keratinisation; (4) a phase of hagocytosis by polymorphonuclear and mononuclear ells; (5) a phase of fibrosis.

Alter[16] studied the histological changes in epithelioma of the cervix uteri after irradiation, and observed hat some growths responded so rapidly that the dissolution of the tumour cells occurred before any cellular changes could be observed—in other words, a direct action of the irradiation. Other growths responded more slowly, and here the basal cells were destroyed, but the prickle cells keratinised in a normal manner, except that this keratinisation was accelerated by repeated small doses of irradiation.

The few cases in which I have been able to observe the changes in an epithelioma consequent upon irradiation have shown in a striking manner the rapid differentiation of the malignant cells into keratinised cells; these latter die and are absorbed by polymorphonuclear phagocytosis. Two cases in which lymphatic glands containing metastases were excised after irradiation showed that the metastases were of a lower histological grade than the primary growth—i.e., had undergone greater differentiation. Alter also observed these changes in lymphatic gland metastases after irradiation.

Thus the action of irradiation upon an epithelioma may be summarised as (1) the actively dividing cells (basal or embryonic type of cell) are destroyed by direct action, and (2) the differentiating, more adult type of cell is speeded up in its differentiation, becomes keratinised and so dies—that is, is destroyed by indirect action.

With regard to the effects of irradiation upon the stroma of a malignant growth, there is an equal division of opinion as to whether changes in the stroma are primary or secondary effects; in general, such changes can be interpreted as similar to the ordinary connective tissue changes by which any lesion in the body is healed.

If, then, irradiation kills some malignant cells and stimulates others to complete adult differentiation, the highly differentiated epithelioma and the very anaplastic one would react equally well to radiotherapy. The cells of the former, or Grade 1 carcinoma, would undergo complete differentiation beyond the point of reproduction. The cells of the latter, or Grade 4 carcinoma, would be killed directly. Thus the interaction of these two factors would explain why irradiation heals the same percentage of growths in each histological grade.

PRACTICAL APPLICATION.

The practical application of this hypothesis would require the coöperation of the pathologist and the radiotherapeutist. It has been suggested that the maximum direct lethal action of irradiation on the cell is obtained by a high intensity acting for a short time, while the indirect action is best obtained by a low intensity acting for a long time.

Now the varying proportions of actively dividing cells, prickle cells, and keratinising cells in an epithelioma can be assessed by Broders's classification, and the problem will consist of the determination of the best method of irradiation according to the histology of the cancer under treatment. If the healing of a Grade 1 carcinoma, consisting mainly of prickle and keratinising cells, requires the differentiation of these into fully keratinised elements, this result will be best obtained by a small dose of irradiation acting for a long time. As an example could be instanced the surface application of radium, the results of which have already been demonstrated in the effective treatment of cancer of the lip; epithelioma of this site is mainly a Grade 1 or 2 growth, and hence its ready healing by prolonged surface application as applied by Regaud and Quick. For Grades 2 and 3 growths, a moderate intensity for a moderate time would be suggested; or perhaps better still would be combined X irradiation (to destroy the dividing cells) and radium (to stimulate differentiation of the prickle cells into non-cancerous keratinised elements). The anaplastic Grade 4 growths would respond to a high intensity for a short time, as by deep X ray therapy; X rays are also indicated for this type of epithelioma, because it has usually extended much more widely than clinical examination would suggest, so making difficult its efficient irradiation by radium implantation.

Summary.

1. The investigation comprises the study of 319 cases of buccal carcinoma from the viewpoints of histology and clinical course, and of 71 cases as regards irradiation response.
2. The accuracy and usefulness of Broders's histological classification of epitheliomata have been demonstrated.
3. A well-marked correlation between the histology and the clinical course of buccal carcinoma has been obtained. This correlation is found especially in (*a*) the post-operative length of life, (*b*) the total duration of the disease, and (*c*) the prospects of cure. These are increased the greater the differentiation of the carcinoma, and decreased the greater its anaplasia.
4. No direct relationship was found between the histology of buccal carcinoma and its response to irradiation.
5. A hypothesis is suggested to explain this apparent exception to the general correlation between the histogenesis and the biology of buccal carcinoma.
6. The possible use of this hypothesis in the radiotherapy of buccal cancer is suggested as enabling the most suitable method of irradiation to be applied according to the histology of the growth.

My thanks are due to the electors of the Luther Holden scholarship, during my tenure of which this work was done; to Mr. G. E. Gask and Dr. E. H. Kettle, professors of surgery and pathology at St. Bartholomew's Hospital, for their constant direction and assistance; and above all to Dr. H. H. Woollard, *professor of anatomy at St. Bartholomew's*, for many fertile discussions and continuous helpful criticism.

TRIGEMINAL NEURALGIA.

THE ANATOMY OF THE "HARTEL" TECHNIQUE.*

By LESLIE MORRIS, M.D. MANCH., F.R.C.S. ENG.,
SURGEON, CITY SANATORIUM, LEICESTER; LATE SURGICAL REGISTRAR, ROYAL INFIRMARY, MANCHESTER.

TRIGEMINAL neuralgia is a progressive intractabl disease. Its chief manifestation is a sudde excruciating pain limited to the area of distributio of the trigeminal nerve. Although the patholog and ætiology of this complaint are still unknown relief can be obtained by interruption of the nerv impulse in its course to the brain. This may be don by an intracranial operation or by an injection alcohol, which destroys the function of the nerv through or about its foramen of exit from the skul This paper does not deal with the relative merits the alternative methods; both are skilled procedur and in each case the final success depends upo specialised study and practice.

The first operations (performed with success) we devised simultaneously by Hartley[1] and Krause who removed the Gasserian ganglion itself by temporal route. With this operation there was a hig mortality, and the removal of the ophthalmic divisio of the ganglion frequently caused injury to t cavernous sinus, and also led to a trophic keratit For these reasons Hutchinson[3] advocated a parti resection of the ganglion which left intact t ophthalmic division and the adjacent sinus. In 1S Spiller,[4] as a result of a series of experiments, show that division of the sensory root of the gangli relieved the condition as effectively as removal of t ganglion with a lower mortality, no danger to t cavernous sinus, and less risk of keratitis. Since th date the division of the sensory root of the Gasseri ganglion has been practised with great success. the present time Frazier[5] advocates a partial secti of the root, and preserves the ophthalmic fibr which he believes are morphologically distinc Adson,[7] on the other hand, preserves the motor ro because he believes that neuralgia affecting t ophthalmic division is more prevalent than is oft thought. This is a difficult and serious operatio but can undoubtedly be regarded as successful the hands of the above surgeons the mortality less than 1 per cent. and the relief certain. F surgeons, however, have the time, opportunity, enough cases to enable them to achieve this deg of proficiency. Because of this, alternative a simpler methods based on alcoholic injections ha been developed, and it is the opinion of the writ that such methods give an equal chance of succe with few dangers and no mortality.

The treatment by alcoholic injection falls into tw groups. The one aims at a temporary destruction the function of the nerve at its foramen of exit fr the skull, the other at a permanent result by acti on the Gasserian ganglion itself. The first group w not be considered in this paper, but it may be me tioned that the temporary relief obtained by t method is an important accessory, both as a mea of diagnosis and treatment, to the more radic injection.

The second method depends upon the injecti reaching the Gasserian ganglion by way of th foramen ovale. There are two routes, the [illegible] transzygomatic one advocated in this country

---

* Based on a paper read to the Society of British Neurolog Surgeons, Manchester, 1927.

Harris,[8] and the ascending extrabuccal route which was perfected by Hartel in Germany.[9] In 1909 Harris, while attempting to block the mandibular nerve at the foramen ovale, noticed that the injection sometimes caused anæsthesia in all the branches of the ganglion. But it was not until the publication of Hartel's paper in 1913 that a more certain method of anæsthetising the ganglion was demonstrated. In this work Hartel established the necessary technique and made a great advance on the methods of his predecessors. Without a thorough knowledge of German it is difficult to appreciate the significance of Hartel's work, and for this reason the writer has worked out the whole technique from first principles. The results, which are detailed in the following pages, closely follow those of Hartel and generally confirm his conclusions; on the other hand, certain differences have emerged and consideration is given to their interpretation.

The Hartel Injection.

Hartel found that if a needle is passed through the foramen ovale in the plane of the axis of the Gasserian ganglion it reaches the skin near the angle of the mouth. He then retraced from the outside the course of the needle and, by inserting it about the level of the upper mid-molar tooth, traversed the tissues around the mucous membrane of the mouth (guided with a finger in the mouth) until the point of the needle reached the area of bone in front and to the outer side of the foramen ovale. This surface of bone he considered was so characteristically hard and smooth that it could be used as a landmark to the foramen, which was the first depression or irregularity met with on it in working the point of the needle backwards. In this way he showed that the foramen ovale, and in consequence the Gasserian ganglion, could be located with accuracy.

Anatomical Observations.

In order to obtain a safe and accurate manipulation by this method it is necessary to examine: (1) The anatomical relations of the needle. (2) The anatomy of the skull around the foramen ovale, and especially those points which would enable one to locate the foramen by palpation with the point of a needle. These relationships are dealt with in the following paragraphs. The results given are based on work performed on the one hand in the Anatomy Department of the University of Manchester, and on the other hand in the Museum of the Royal College of Surgeons of England.

STRUCTURES LYING IN RELATION TO A NEEDLE PLACED IN LINE FROM THE ANGLE OF THE MOUTH TO THE FORAMEN OVALE.

These were ascertained from a series of dissections performed around a needle placed in the above axis. Fundamentally it was found that the needle takes a route between two planes: an internal one, which is soft and flexible and consists of the buccinator muscle and the mucous membrane of the mouth; and an external one, which is resistant and is formed by the mandible and the muscles attached to it. It will be apparent that no structure of importance is likely to lie between two such mobile planes, and this is confirmed by dissection—the space being filled entirely by a pad of fat known as the "fatty ball of Bichat."

The course taken by the needle is as follows. First it pierces the skin and superficial fat for about a centimetre, then, after crossing the few fibres of the muscles of expression, it enters the fatty ball of Bichat and traverses it in its long axis for at least 3 cm. Finally, leaving the fat, the needle reaches the external pterygoid muscle, and pursuing an oblique course crosses it for the last centimetre to reach the foramen ovale. From this it is evident that there is little danger of injury to important structures in the direct path of the needle, and consideration must now be given to those which lie near the path.

1. The *facial artery* runs in the plane of the muscles of expression about 1 cm. external to the angle of the mouth. The needle should, therefore, always be inserted still more external to the artery, so as not to injure it. Similarly the facial vein, which runs just external to the artery, should be respected. It is obvious that infection of the vein and phlebitis extending to the cavernous sinus, although never yet recorded, would be most serious.

2. The *parotid duct* arches round the anterior border of the mandible and crosses the fatty ball of Bichat to reach the mucous membrane of the mouth. Its course crosses that of the needle at a right angle. On these occasions it may conceivably be pushed aside, as there is no record of its injury or a fistula resulting.

3. The *internal maxillary artery* may take one of two courses with almost equal frequency: one deep, the other superficial to the external pterygoid muscle. When it takes a superficial course it may be injured by the needle. If so, a hæmatoma forms at once. This can readily be stopped by pressure, and the needle must be removed and inserted in another plane. In one dissection the artery took a course deep both to the muscle and to the underlying mandibular nerve, a position perfectly safe from the standpoint under consideration.

4. The *middle meningeal artery* takes a course behind the foramen ovale and, as will be emphasised later, behind the sphere of action of the needle. In 5 per cent. of cases it replaces the small meningeal artery and goes through the foramen ovale, where it might conceivably be injured. This accident is again of no practical importance, since the hæmorrhage resulting would be extracranial, and an intracranial hæmorrhage or other injury has yet to be placed on record.

5. The *Eustachian tube.*—Hartel and others consider that there is danger to this structure if the needle is manipulated deep to the foramen ovale. Observations, however, reveal two important points. First, the Eustachian tube from mouth to ear takes a course upwards, backwards, and outwards, so that the needle running in a direction upwards, backwards, and inwards would tend to glide off the tube rather than to pierce it. Secondly, the tube takes an oblique course at least 1 cm. below the foramen ovale, and forms one side of a triangle with the base of the skull and the external pterygoid plate respectively as the other sides. From this, a needle which passes deep to the foramen ovale would engage in the tissues in this triangular space and so ride above the tube. For these reasons I do not consider that the Eustachian tube is liable to be injured during these manipulations.

6. The *mandibular nerve* was found to take a course directed downwards and backwards, forming an angle of nearly 90 degrees with the external pterygoid plate. This is important when the nerve is to be located by the horizontal route through the sigmoid notch. It is evident that, unless the nerve is located at the foramen ovale itself, any other manipulation is useless. Furthermore, the nerve may run deep to the accessory ossifications in this region, and at a depth which makes its safe infiltration with alcohol impossible.

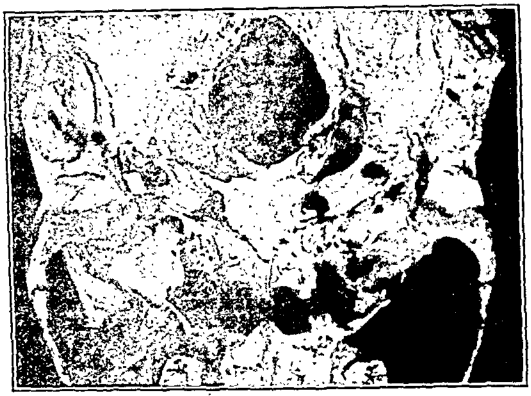
One may say, therefore, that the structures lying near to the path of the needle are unlikely to be injured, and also that no harm will result if they are actually pierced. The path of the needle itself is almost entirely through fatty tissue, and the internal maxillary artery is the only structure of importance which may occasionally lie in the direct path of the needle and in that event cannot be avoided.

THE FORAMEN OVALE AND ITS LOCALISATION.

An examination of the base of the skull shows that nothing of importance lies antero-external to the foramen ovale, whereas postero-internal lie many vital structures (Fig. 1). Hence it is advisable that any manipulation of the needle in these operations should be made in the former area. Hartel himself emphasised the fact that, if a needle is guided on to the infratemporal surface of the temporal bone, a surface smooth and hard, careful manipulation backwards would detect the foramen ovale as the first irregularity on that surface. On the other hand, Purves-Stewart[10] pointed out the value of the external pterygoid plate as a guide.

The following is a summary of my own observations and deductions on the above factors, made independently of the publications of these authorities

FIG. 1.



Base of skull, showing relations of the foramen ovale.

OBSERVATIONS MADE IN AN EXAMINATION OF 200 SKULLS.

1. The *foramen ovale* is never absent. It varies in size and shape, and in 2 per cent. of cases is so small as to make penetration by a needle impossible.

2. The *foramen spinosum* in 4½ per cent. of cases is small or absent. On these occasions it is probable that the middle meningeal artery goes through the foramen ovale.

3. The *infratemporal surface of the sphenoid bone* is smooth and hard. In two cases it was irregular, and in these a fossa was present large enough to be mistaken for the foramen ovale. When this occurs, localisation of the foramen is practically impossible (Fig. 2).

4. The *external pterygoid plate* is a muscular process, and as such is irregular in shape. For practical purposes, however, it may be considered to be rectangular. It is triangular or receding in shape in 6 per cent. of cases, and either very narrow or very broad in 2 per cent. The interest in this plate is the relation of its base to the foramen ovale. The base usually lies immediately in front of the foramen, but when the plate is very narrow this relation does not hold good, and the plate may be as much as 1 cm. in front of the foramen. The relation also may be considered to be inconstant when the border of the plate recedes. At the base of the external pterygoid plate there are accessory attachments of the external pterygoid muscle, and these may become ossified. Of the two types of ossification which have been described by Mackay[11] (Fig. 3):—

(*a*) The *pterygo-sphenoid* is a small ridge of bone which runs from the base of the external pterygoid plate on to the infratemporal surface of the sphenoid bone. It occurs with a 1 per cent. frequency only, and is not of importance.

(*b*) The *pterygo-spinous* is a more marked ridge of bone. It may be either complete or incomplete, and extends from halfway up the margin of the external pterygoid plate to the spine of the sphenoid. The writer found that this bridge of bone may take one of two positions; either deep or superficial to the spine of the sphenoid, and in consequence deep or superficial to the foramen ovale, the frequency being 5 per cent. and 1 per cent. respectively. Thus, in the greater percentage of cases, this ossification, which seemingly is in such intimate relation with the foramen ovale, is deep to it and is actually out of the area of manipulation with the point of the needle.

It has now been shown that the infratemporal surface of the sphenoid bone is consistently smooth and hard, and that the base of the external pterygoid plate is in constant relation to the foramen ovale. The conclusion is drawn that the foramen ovale is best and most safely located if use is made of both these points and the depth of the foramen is estimated from the foramen surface, and its position backwards from the latter plate. The technique of injection based on this will be described in detail elsewhere.

The 400 observations made by the writer show that this method would have resulted in failure only to the following extent, and for the reasons stated:—

	Times.	Per cent.
1. A small foramen ovale	8	2
2. A superficial pterygo-sphenoid ossification..	4	1

and there would also have been difficulty to the following extent and for the following reasons:—

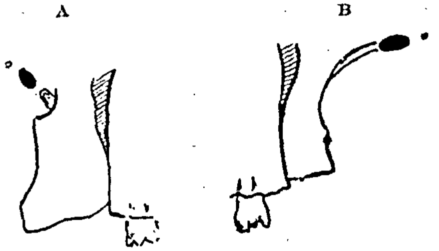
	Times.	Per cent.
1. A narrow external pterygoid plate ..	4	1
2. A fossa on the infratemporal surface of the sphenoid bone	2	½
3. The presence of an accessory ossification ..	20	5

The injections performed at autopsy, as detailed below, will be seen to confirm these figures.

OBSERVATIONS MADE AS A RESULT OF INJECTIONS PERFORMED AT AUTOPSY.

These were made from a series of 100 injections, 51 of which, including any case in which difficulty was experienced, were confirmed and recorded after removal of the skull cap. The other 49 were so straightforward that such confirmation was not carried out. The technique used was that of Hartel. The skin puncture was made 1–2 cm. lateral to the angle of the mouth, or 2–3 cm. above this point, the former being referred to as the "vertical" type, the latter as the "horizontal" type. The point of the needle was guided between the buccinator muscle and the mandible on to the infratemporal surface of the sphenoid bone, and with the aid of this surface and of the adjacent external pterygoid plate the foramen ovale was localised.

FIG. 2.



External pterygoid plate. (A) Fossa at base; (B) receding type.

In the 51 recorded cases:—

(*a*) The ganglion was accurately located in 47.

(*b*) Difficulty was experienced in five, and only when the more horizontal injection was performed.

(*c*) The dura was pierced twice, and with the vertical injection only.

(*d*) The *sphenomaxillary fissure* was reached on one occasion, and the error recognised and corrected at the time.

(*e*) Failure occurred in four cases, 4 per cent. of the whole series.

The causes of failure were: (1) A depression which was present on the infratemporal surface of the sphenoid bone. The piece of bone was removed for examination and this depression was found to lie just in front of the foramen ovale, and to resemble it in size and shape. The foramen itself was normal, but it was impossible to ignore the irregularity lying in front of it (Fig. 2). (2) A foramen ovale too small to admit the point of the needle. (3) and (4) Fibrosis round the foramen too dense to pierce unless undue force was used.

(*f*) When inside the skull, the needle lay in the axis of the third division of the ganglion and, if pushed in further, reached the sensory root of the ganglion. In five cases only did it tend to approach the second division, and in these cases it ran under the division.

The motor root of the ganglion was in all cases untouched (*Fig.* 4).

Discussion.

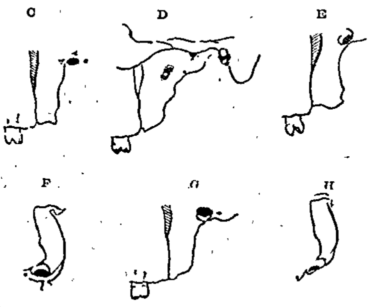
Evidence has accumulated during the course of the present investigation to suggest that what is called "injection of alcohol into the Gasserian ganglion" does not describe what actually happens, and that the alcohol affects the sensory root of the ganglion more than the ganglionic tissue itself.

This evidence may be outlined as follows:—*Anatomical:* (*a*) The planes in which the ganglion and its division lie; (*b*) the shape and character of the foramen ovale; (*c*) the plane in which the needle runs; (*d*) the attachments of the dura mater to the ganglion. *Experimental:* The course seen to be taken by dyes injected into the region of the ganglion. *Clinical:* (*a*) The areas of anæsthesia following injection; (*b*) the interpretation of the nerve paralyses following injection.

ANATOMICAL EVIDENCE.

(*a*) Within the middle fossa of the skull there is a groove on the petrous portion of the temporal bone over which runs the sensory root of the Gasserian ganglion. The ganglion itself, lying in a continuation of the groove, is really formed by the convergence of its three divisions. Of these divisions the third is seen to be in direct continuity with the sensory root and leaves the skull at the foramen ovale; the first forms an angle of almost 60 degrees with the third and takes a horizontal course to the sphenoidal fissure; the second lies between the two, nearer and on a similar plane to the first division. In other words, the first and second divisions of the ganglion do not lie in continuity or in the same plane as the sensory root, whereas the third division may be considered to do so.

FIG. 3.



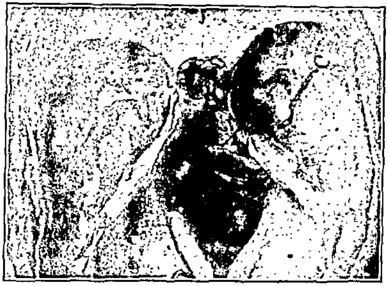
External pterygoid plate with accessory ossifications. (C) Pterygo-sphenoid. (D) Pterygo-spinous: complete deep; (E) complete superficial; (F) partial superficial (from within); (G) partial deep; (H) partial deep (from within).

(*b*) The foramen ovale is a channel in the sphenoid bone for the passage out of the skull of the third division of the ganglion. It may be regarded as a cylinder, and from its formation its axis is that of the nerve and, therefore, that of the sensory root.

(*c*) Thus, a needle entering the foramen ovale by the Hartel route (i.e., in the axis of the ganglion) will tend to take a natural route through the central axis of the foramen, along the third division to the ganglion, and then into the sensory root itself—a deduction confirmed by injections on the cadaver.

Variations from this central route do occur, but are not common, and in most cases can be avoided. The variations are as follows. When the axis is more vertical than usual, the needle may reach the dura mater, cerebro-spinal fluid is seen to escape, and the error can then be rectified. When it is more horizontal its course is limited by the shape of the foramen, and it is almost an anatomical impossibility to take a course deep to the nerve and in relation to the periosteum. A lateral deviation of the needle is possible, and may account for some of the irregular results obtained in these cases. The medial deviation, because of the direction of the needle, is impossible.

FIG. 4.



Dura mater reflected to show Gasserian ganglion with wire representing needle in situ (x—x).

From this it may be suggested that, if the most horizontal direction in which the needle will pierce the foramen is aimed at, the cylindrical shape of the foramen makes it almost a certainty that the correct axis will be maintained. In these cases the sensory root can actually be reached with the point of the needle without danger.

The series of 51 Hartel injections (performed at autopsy) gave the following comparative results:—

1. In 21 "*vertical*" injections: No difficulty was experienced; the dura was pierced twice; the point of the needle deviated five times from the axis of the sensory root.
2. In 30 "*horizontal*" injections: Difficulty was experienced five times; the dura was never pierced; the axis of the sensory root was always maintained accurately.

These results indicate that it is an anatomical probability that the point of the needle in the Hartel injection will tend to reach the sensory root of the ganglion if it is pushed through the foramen ovale far enough.

Two layers of dura mater cover the Gasserian ganglion, forming what is known as the cave of Meckel. The dura is definitely adherent to the ganglion, but not to its sensory root or to the divisions. From this an "hour-glass" effect on the accumulation of alcohol can be conceived. If the alcohol is injected just inside the foramen ovale and into the fibres of the third division of the ganglion, it will first of all tend to accumulate between the ganglion and the foramen ovale; then, limited by the attachment of the dura to the ganglion, will pass along the division, along the postero-external part of the ganglion, and into the region of the sensory root, where it is again possible for it to accumulate. Thus the alcohol may reach the sensory root without it being necessary for the point of the needle to do so. An eccentric puncture, with the point of the needle actually in the ganglionic tissue itself, will be necessary to anæsthetise other parts of the ganglion than its external margin.

EXPERIMENTAL EVIDENCE.

The following evidence is derived from observation of the course seen to be taken by dyes injected into the region of the ganglion. When a watery solution of a dye is injected through the foramen ovale into the region of the ganglion, it diffuses so readily that the observation is of little value except as showing that the dye flows to the sensory root. By using a gelatin mass stain, however, the course of the spread of the dye can be observed, and it is possible to examine the nerve tissue thus affected.

When a small amount of this stain was injected slowly, it was seen that it accumulated central to the point of the needle and apparently in the ganglion itself. Later section of the nerve tissue, however, revealed that it was not in the ganglionic tissue that *the stain lay, but in between the fibres of its root.* When larger quantities were injected more rapidly, the whole area became flooded with the stain, which spread along the sensory root and into the posterior fossa of the skull.

CLINICAL EVIDENCE.

The following table, based on a series of 25 injections performed by the writer, shows the areas of anæsthesia which resulted, and the occasional nerve complications which arose.

Case No.	Anæsthesia in division.	Complications.	Case No.	Anæsthesia in division.	Complications.
1	3	—	15	1, 2, 3	—
3	3	—	16	1, 2,	K.
4	3	—	17	1, 3	—
6	1, 2, 3	6	18	1, 2, 3	—
7	3	—	19	1, 2, 3	—
8	3	—	20	1, 2, 3	K.
9	1, 2, 3	6 K.	21	1, 2, 3	—
11	3	—	22	1, 2, 3	—
12	3	—	23	1, 2, 3	K.
13	3	—	24	1, 2, 3	6, 7, 8 K.
14	3	—	25	1, 2, 3	—

From this table it is evident that two groups of anæsthesia result, one affecting the third division alone, the other all three divisions. It is rare for any other combination to occur (actually two cases in 25) and in this sequence the absence of the combined anæsthesia of divisions three and two is notable. It would be expected that, if the ganglionic tissue were involved, irregular areas of anæsthesia, such as divisions three and two, or two and one, would be found. In the circumstances it is reasonable to assume, with the support of the anatomical and experimental evidence outlined, that the combined anæsthesiæ follow effect on the sensory root, whereas the anæsthesia of division three alone is from effect on the peripheral nerve only. This assumption is further supported by the experience that effect on the former tends to be permanent and on the latter temporary.

It will be noted that the sixth cranial nerve was paralysed on three occasions, but never the third or the fourth nerves. This can only be explained if the alcohol spreads along the sensory root of the ganglion and affects the sixth nerve as it leaves the posterior fossa of the skull. The nerve in this situation has been observed in some cases to lie in actual contact with the sensory root. That this is the course taken by the alcohol is finally confirmed by the twenty-fourth case. Here there was a paralysis of both the seventh and eighth nerves as well as of the abducens. This combined anæsthesia is only possible if these nerves are affected at the internal auditory meatus, a foramen lying just below the groove for the sensory root when the head is in the position used in operating. As less than 1 c.cm. of alcohol was injected in this case, it must have spread directly along the sensory root to cause these effects.

In conclusion, the weight of the evidence leave little doubt that the sensory root is more liable t affection than the Gasserian ganglion when th Hartel injection is performed. Elsewhere it will b shown that, as may be expected, the effect on th sensory root may be permanent. Where this is s the results of injection compare favourably wit those of the *major operations.*

Summary.

1. Trigeminal neuralgia may be treated with succe either by operation or by the injection of alcoh into the region of the Gasserian ganglion.

2. The Hartel technique gives a satisfactory meth of reaching the ganglion with certainty.

3. It is shown that the route taken by the need is free from danger, the foramen ovale can be locat with accuracy and safety if its relations to both t infratemporal surface of the sphenoid bone and t external pterygoid plate are appreciated.

4. A high, "horizontal" Hartel route is the m accurate, and with its use it is suggested that it the sensory root, and not the ganglionic tissue itse that is affected by the alcohol. If so, the resu obtained may be expected to be permanent, and compare with those obtained by major operation.

BISMUTH OXYCHLORIDE OINTMEN

IN THE TREATMENT OF

LUPUS ERYTHEMATOSUS.

BY R. M. B. MACKENNA, M.A. CAMB., M.R.C.P. Lo
HON. DERMATOLOGIST, LIVERPOOL STANLEY HOSPITAL.

DURING the last two years dermatologists h taken an increasing interest in the treatment of lu erythematosus with injections of bismuth. So —e.g., Segrè,[1] consider that the results of this line treatment compare favourably with those obtai by the injection of gold salts, and prefer b because it is much less toxic and may be given with risk of aggravating a tuberculous lesion within body.

A survey of the work published on this subj during the last two years shows that the major of workers have relied on injections of bismuth, a have not applied bismuth locally or given it by t mouth. In January, 1930, I stated[2] that I had n been able to obtain satisfactory results by t administration of bismuth oxycarbonate or bismuth salicylate per os, and that local applications of Suspensol (a colloidal preparation of metallic bismuth in an ointment basis) had not, in my hands, given satisfactory results. I recorded one case in which satisfactory results had been obtained by the use of 5 per cent. colloidal bismuth oxychloride ointment.

In Europe, inunction with mercury has been used as a treatment for syphilis since 1497, and it was therefore almost inevitable that, as bismuth commenced to supplant mercury in the treatment of this disease, attempts should be made to administer bismuth by inunction. Certain syphilologists have reported favourably on this method of administration; others have categorically asserted that the amount of bismuth absorbed is insufficient to produce any therapeutic effect. The question is still sub judice but, as it had been shown by Nicolas, Lacassagne, and Rousset[3] that injections of bismuth would cure lupus erythematosus, it seemed rational to suppose that good results might be obtained by applying bismuth ointment locally. I therefore prescribed suspensol in several cases of lupus erythematosus, but was not satisfied with the results obtained.

It is generally accepted that oxychloride of bismuth injected intramuscularly is absorbed more readily by the organism than metallic bismuth. It therefore seemed to be feasible to conduct experiments with an ointment containing bismuth oxychloride, preferably in a colloidal state. After many experiments, a research chemist at the St. Vincent Laboratories, 160, Bath-street, Glasgow, was able to manufacture an ointment containing 5 per cent. of the salt in the required colloidal state, and the results obtained by the use of this ointment as a local application for chronic lupus erythematosus have been satisfactory. Clinical trial showed that, in the majority of cases, better results were obtained if the bismuth oxychloride content was increased to 10 per cent. The ointment has been put on the market by the above-named laboratories under the trade name of Bismurung. It is, perhaps, advisable to add that I have no financial interest in its sale.

Results in Lupus Erythematosus.

In all cases the ointment has been applied freely and rubbed with moderate vigour on to each of the affected areas for at least two minutes twice daily. In a few cases of lupus erythematosus it has caused slight irritation and itching of the affected part, but when rubbed into healthy skin it has never caused any local irritation. It has now been prescribed for 19 cases of lupus erythematosus and in none has its application had any but beneficial results. In the majority, injections of bismuth or bismuth salts have been given at fortnightly or monthly intervals in order to intensify the action of the ointment, but although I can quote but one case (No. 11) of lupus erythematosus which has been apparently cured by the use of the ointment alone, this is merely because this line of treatment has only been under investigation during the last 12 months. I am, however, convinced that the average case of this disease can be cured by the persevering application of the ointment alone, but the time in which a cure may be obtained can be shortened by giving a few injections of one of the usual bismuth preparations. Conversely, the use of the ointment reduces the number of injections of bismuth necessary for cure, and incidentally ensures that healing will take place without the formation of a scar.

The following is a brief record of ten of the most typical cases which have been treated:—

CASE 1.—Mr. A., aged 40, had been treated since 1928 with local applications of acid nitrate of mercury for numerous discoid patches of lupus erythematosus affecting the left cheek and the left side of the neck. From July 8th, 1929, to Jan. 11th, 1930, he received a total of 4·6 g. of metallic bismuth intramuscularly. Progress under this line of treatment was disappointing. From Jan. 17th, 1930, to May 30th, 1930, 10 per cent. bismuth oxychloride ointment has been used and he has received only 0·8 g. of metallic bismuth intramuscularly during this period. Three of the discoid patches have disappeared and the remainder are fading.

CASE 2.—Miss B., aged 26, had severe lupus erythematosus affecting the whole of both cheeks, the nose and forehead, and a few discoid lesions of the scalp. From July, 1927, to April, 1929, she had received much local treatment with ultra-violet light. Salicin had been administered internally, and numerous external applications had been prescribed. From April 13th to Dec. 7th, 1929, she received 4·8 g. of bismuth and 1·5 g. of bismuth oxychloride deep subcutaneously. Great improvement took place during October and November, and in January, 1930, it was confidently anticipated that she would be cured within a few weeks. During January and February, 1930, no improvement whatsoever occurred, despite the deep subcutaneous administration of 1·2 g. of bismuth oxychloride. On Feb. 27th she was given 10 per cent. bismuth oxychloride ointment, and was pronounced cured on June 24th, having only received two injections each of 0·4 g. of bismuth oxychloride between Feb. 27th and June, 1930. There is now no scarring of the previously affected parts, and the skin appears to be absolutely normal.

CASE 3.—Miss C., aged 29, had been treated since 1923 for lupus erythematosus affecting the nose and cheeks. The areas had been treated with carbon dioxide snow, acid nitrate of mercury, and various ointments. From Oct. 2nd, 1927, to Jan. 31st, 1930, she received a total of 2·4 g. of metallic bismuth and 3·6 g. of bismuth oxychloride deep subcutaneously. The cheeks became normal during December, 1929, but the condition of the nose remained unchanged. On Jan. 31st, 1930, 5 per cent. bismuth oxychloride ointment was prescribed and applied to the nose twice daily. By April 9th only slight progress had been made, and she was given a 10 per cent. ointment. She was discharged as cured on June 21st, 1930.

CASE 4.—Miss D. had lupus erythematosus (the lesions being vividly erythematous) affecting the eyelids and nose and extending downwards over the cheeks to a distance of one inch from the eyes. From July to October, 1929, a total of 4·8 g. of metallic bismuth was given by injection. No improvement resulted. From November to December 1·6 g. of bismuth oxychloride were injected. Slight improvement then occurred, and the edges of the lesions began to clear up. No marked improvement occurred until Dec. 14th, 1929, when the patient was given 5 per cent. bismuth oxychloride ointment; considerable improvement was seen during the ensuing 14 days. She has received no injections since December. The strength of the ointment was increased to 10 per cent. in March, 1930. When last seen on June 2nd she reported that progress had been slow but continuous. The edges of the lesions were slowly receding and healing had taken place in the central portions of the affected areas. No scarring had occurred.

CASE 5.—Mrs. E., aged 60, had scattered discoid lesions of lupus erythematosus on the forehead, nose, cheeks, and neck. The distribution was bilaterally symmetrical and the scalp was not affected. The eruption had been present for two years. When first seen on March 4th, 1930, she was given an injection of 1 c.cm. of bismogenol, and 5 per cent. bismuth oxychloride ointment was prescribed. Almost immediately she began to improve. The injection was repeated once every fortnight until May 27th, when the lesions had almost disappeared. When last seen on July 27th she was discharged as cured.

CASE 6.—Miss F., aged 34, had lupus erythematosus of the hands of unknown duration. From April 10th, 1929, to May 21st, 1930, a total of 3·4 g. of metallic bismuth was given intramuscularly. The condition improved slowly until Feb. 1st, 1930, when 10 per cent. bismuth oxychloride ointment was prescribed. Progress has since been slightly more rapid, but the patient is not yet cured.

CASE 7.—Mrs. G., aged 31, had lupus erythematosus, affecting the conchæ of both ears, diagnosed in November, 1928. A small area immediately anterior to the left ear was also affected. During 1929 she received a considerable amount of treatment with ultra-violet light, painting with acid nitrate of mercury, &c. No improvement occurred. During December, 1929, she received a total of 0·8 g. of bismuth oxychloride, but thereafter she refused to have any more injections. The lesions did not improve until she was given a 5 per cent. bismuth oxychloride ointment. By May 7th, 1930, the patch on the cheek had disappeared, leaving no scar, and the affected areas on the ears were practically cured. The 10 per cent. ointment was then prescribed, and six weeks later the right ear and the cheek were completely cured. The concha of the left ear is still affected.

CASE 8.—Mr. H., aged 45, had lupus erythematosus of 18 months' duration in typical bat's-wing distribution. He was first seen on April 17th, 1930. An injection of 0·3 g. of bismuth oxychloride was given and 10 per cent. bismuth oxychloride ointment was prescribed. When next seen on May 9th the eruption on the nose had disappeared and three-quarters of the previously affected areas of the cheeks were normal, the lesions having faded, leaving no scar. Another injection of bismuth oxychloride was given and the patient has not returned for further treatment.

CASE 9.—A spinster, aged 27, had had two small areas of lupus erythematosus on the nose and right cheek for five months. An injection of 0·3 g. bismuth oxychloride was given when the patient was first seen on May 14th, 1930, and 10 per cent. bismuth oxychloride ointment was prescribed. When seen a month later the lesions had practically disappeared.

CASE 10.—Miss I., aged 41, had lupus erythematosus of the face in bat's-wing distribution and the fingers were also affected. There was a two years' history when she came for treatment on March 17th, 1930. 1 c.cm. of bismogenol was given intramuscularly, and 10 per cent. bismuth oxychloride ointment was prescribed. A month later she had improved considerably, and the injection was repeated. On May 17th the face was pronounced cured, and the condition of the hands had greatly improved.

DISCUSSION.

In the typical cases of bat's-wing lupus erythematosus I have found that treatment by injection alone will, in time, produce a cure, but the surface of the skin of the previously affected area remains slightly "rough," the "roughness" apparently being due to a slight degree of hyperkeratosis. If, when the injections are discontinued, the ointment is applied the skin rapidly becomes normal in all respects. In a previous paper [2] I suggested that "any improvement in a case
of lupus erythematosus after the injection o bismuth,
or bismuth salts, is probably due to the proj which
bismuth possesses in preventing the t from
reacting normally to the toxins (or bact hich
cause the symptoms of the disease. ld
therefore expect that the persons w n
apparently cured will sooner or later e
rence of the lesions." Only one case wh
as being cured has returned with fresh

CASE 11.—Mrs. G., aged 39, first se
1929, presented two small rounded are
matosus on the forehead and left temp
present for 17 months. At irregular
ensuing four months she received a to
intramuscularly. On Sept. 10th, 1929, s
cured, but on March 15th, 1930, she return
that during the previous three weeks the
recommenced. She presented two small patch s
erythematosus on exactly the same areas as had previously been affected. She was ordered 10 per cent. bismuth oxychloride ointment, no injection being given, and a month later she reported for examination and appeared to be cured.

This case seems to suggest that the prompt use of the ointment can abort a relapse of the disease.

There has, unfortunately, been no opportunity for using the ointment in a case of acute lupus erythematosus, and I have been unable to find any record of the treatment of a case of this disease with bismuth. In my opinion the most satisfactory line of treatment would be to administer deep-sub-
been osly, as frequently as possible, a water-soluble
with the lt—e.g., sodium-bismuth-thioglycollate—
by the alt be *rapidly absorbed*, and to apply 10 per cent. oxychloride of bismuth ointment to the affected areas (or to a large part of the affected area) of the skin. This line of treatment might, perhaps, reduce the high percentage of mortality of these cases, and would probably prevent the common sequelæ in those patients who do recover—viz., the development of chronic lupus erythematosus, or the production of cicatricial atrophy of the skin of the affected parts.

Other Uses of the Ointment.

The ointment has been used in a few cases othe than lupus erythematosus. Two cases of lupu vulgaris were aggravated by it. As was expected, n response was obtained in a case of lichen ruber planu affecting the legs. Two cases of pustular folliculiti of the neck cleared up within 48 hours of the applica tion of the ointment, but one would have expected th same result from ung. hydrarg. ammon. dil. Neverthe less these two cases seem to show that the ointmen has a certain antiseptic effect. This suppositio is to a slight degree confirmed by the following cases:—

CASE 12.—Mrs. K., aged 70, had suffered since Septembe 1927, from tinea unguium affecting three fingers of the righ hand. Antiseptic applications, ranging from ichthyo to mercurochrome, and including various forms of iodine have been used. Ointments have also been applied. Owin to the patient's age it has not been considered advisabl to remove the nails. The disease has been extremel resistant to treatment, but the condition of the nails ha steadily improved since March, 1930, when bismuth oxy chloride ointment, 10 per cent., was prescribed.

CASE 13.—Miss L., aged 20, has tinea of the nail of th first finger of the right hand. Since June, 1929, a larg number of the usual antiseptic applications have been use The condition has from time to time improved, only to relaps On May 9th bismuth oxychloride, 10 per cent., was prescribe and the condition of the nail has steadily improved. Ther has not been any relapse since that date.

CASE 14.—Mr. M., aged 35, with no previous history venereal disease, who denied extra-marital congress, ha marital congress on May 1st. On May 8th two small sor were first noticed on the inner side of the prepuce. The spread rapidly, and he reported at hospital on the 12t On examination the sores were found to be non-indurat and in all respects typical chancroids. The Wasserman reaction was negative. Serum from the sores was examine microscopically, but no *Spirochæta pallida* were foun Saline baths were prescribed, and on May 19th furth microscopical examination failed to reveal the presen of *S. pallida*. The lesions were spreading, and by th date were each about 1·2 cm. in diameter. Saline bath were continued, but as no *S. pallida* were found, and as th sores were enlarging, washes of perchloride of mercur 1/3000, and ung. hydrarg. (half strength) were prescribed o May 29th. The chancroids slowly increased in size, despit this treatment, until June 12th, when bismuth oxychlori ntment, 10 per cent., was prescribed, to be applied twic ily. By June 19th one of the ulcers was complete aled, and the second ulcer was healed by June 26th he Wassermann reaction on June 26th was negativ

CASE 15.—An unmarried man, aged 31. contracted gonorrhœa in 1928, and was discharged as cured after three months' treatment. Exposure to venereal infection occurred on May 15th, 1930, when there had been no previous exposure for at least four months. On the 20th he noticed a sore on the prepuce and reported for treatment on the 22nd. He then presented a small non-indurated irregular preputial sore, associated with a slight enlargement of the inguinal glands. Microscopical examination failed to reveal the presence of *S. pallida*. The Wassermann reaction was, however, positive. Lotio hydrarg. perchlor., 1/3000, was prescribed as a local application. On May 29th an injection of neosalvarsan, 0·45 g., was given, and as the sore had not responded to the treatment but had enlarged slowly bismuth oxychloride ointment was prescribed. The injection of neosalvarsan was repeated on June 5th, 12th, and 29th, and the sore healed on or about July 1st. Antisyphilitic treatment was continued, bismuth injections also being given. A tentative diagnosis of chancroid in a syphilitic patient was made.

The cases quoted seem to show that the ointment may be of value in cases of tinea unguium and of chancroid. It has not been employed in cases of syphilis, but it may be presumed that it has a certain use as an application to primary chancres, condylomata, and, perhaps, to the rashes of secondary syphilis in order to diminish the infectivity thereof during the latent period between the administration of arsenobenzol and the disappearance of the visible symptoms of the disease.

The ointment has been found of some value in hastening the absorption of gummatous lesions of the skin:—

CASE 16.—A steward, aged 38, contracted syphilis five years ago, but received no arsenobenzol treatment. When seen on March 31st, 1930, he presented multiple gummata on the forearms and on the back of the left hand. The Wassermann reaction was strongly positive. During April he received a total quantity of 2·25 g. novarsenobenzol intravenously and 0·9 g. of bismuth oxychloride intramuscularly. As a local application ung. hydrargyri, half strength, was given. The gummata rapidly decreased in size, but disfiguring blue marks remained on the skin. Routine antisyphilitic treatment was continued, and on May 5th bismuth oxychloride ointment, 10 per cent., was prescribed as a local application. Fourteen days later the skin of the affected area was normal in colour and the last traces of the gummata had disappeared.

It is suggested that the bismuth oxychloride ointment may be found of use in the treatment of yaws.

Bismuth Inunction.

As Sequeira[4] has said, "stereotyped routine" in the treatment of syphilis "has given place to a plasticity which indicates a tardy appreciation of accumulated experience," and one of the results of this plasticity is that the administration of mercury by inunction is but seldom advocated by the syphilologists of this country. Nevertheless, the majority of neurologists agree that, in cases of pre-ataxic and early ataxic tabes, better results may be obtained by a judicious employment of "mercury rubbing" and neoarsenobenzol therapy than by the employment of neoarsenobenzol and mercury or bismuth injections. It seemed, therefore, that it was of interest to determine whether or not the colloidal bismuth oxychloride in the ointment was absorbed by the skin in sufficient quantities to make bismuth inunctions a feasible proposition. To this end the writer requested the services of Mr. Arthur Padley of Liverpool, who for the last 25 years has had a very considerable experience of the Aachen technique of mercury rubbings. On the first occasion a drachm of 10 per cent. bismurung was rubbed into the back of a healthy male patient for 20 minutes. The total urine for the ensuing 24 hours was collected, but no bismuth was found to be present in the urine, although four hours after the rubbing the patient complained of a metallic taste in the mouth. The experiment was repeated on the same person a fortnight later. The saliva and the urine were both analysed, but no bismuth was found in any specimens taken up to 40 hours after the rubbing.

A 20 per cent. bismurung was obtained, and two males submitted to rubbings. One of them, aged 21, 6 ft. 1 in. in height and 150 lb. in weight was healthy. The other, aged 23, 5 ft. 4 in. in height, weighing 10 st., was suffering from chancroid but was otherwise healthy. Mr. Padley rubbed these two patients with one drachm of 20 per cent. bismurung ointment daily for one week. The rubbing was most thorough, and lasted for 20 minutes on each occasion, various areas of the body being treated on different days, in accordance with the Aachen technique. No ill-effects were complained of by the patients, who were invigorated by the massage, and the ointment did not cause any irritation of the body, even on the hairy areas of the legs. The total urine passed by the patients each day for a week was collected and mixed and was then sent to Miss E. Sadler, M.Sc., of the Department of Pharmacology of Liverpool University, for analysis. Only very small amounts of bismuth were found in the urine. As a control to this experiment the urine taken from three different patients who had received intramuscular injections of bismuth oxychloride was subjected to analysis, and Miss Sadler had no difficulty, not only in detecting the presence of bismuth, but also in estimating quantitatively the amount thereof in the samples. The following table shows in detail the results of this experiment:—

Data.—In 1 drachm of 20 per cent. bismurung there is approximately 0·78 g. of bismuth oxychloride; 0·78 g. of bismuth oxychloride contains 0·0265 g. of bismuth:—

Case A.

Day.	Total amount of urine passed in 24 hours.	Amount of total daily output of urine examined.	Amount of bismuth found.	Total amount of bismuth excreted in 24 hours.	Concentration of bismuth in mg. per 100 c.cm. urine.
	c.cm.	c.cm.	mg.	mg.	mg.

This experiment seems to show that, while bismurung may be of some value as a local application in the treatment of syphilis, it is valueless if used as an inunction.

Summary.

(1) A preliminary report has been submitted upon the treatment of chronic lupus erythematosus with bismuth oxychloride ointment. (2) Of a series of 19 cases of chronic lupus erythematosus, all of which have benefited from the use of the ointment, ten have been reported in detail. Of these, five have been cured by the use of the ointment, in conjunction with injections of bismuth, and the clinical reports indicate that in many cases the disease may be cured by the local application of the ointment, without injections of bismuth. (3) Cases have been quoted showing that the ointment appears to have a slight antiseptic or bactericidal effect; the ointment has been employed with advantage in two cases of tinea unguium and two cases diagnosed as chancroid. (4) It is shown that, while the ointment may be of value as a local application in the treatment of yaws and syphilis, it is valueless if administered by inunction.

It is my pleasant duty to acknowledge my indebtedness to Prof. W. J. Dilling and to Miss E. Sadler, of the Pharmacological Department of Liverpool University, for their assistance in the laboratory work detailed in this paper.

MEDICAL SOCIETIES

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held at the West London Hospital on Jan. 9th, with Dr. H. H. SANGUINETTI, the President, in the chair, when a discussion was held on

Malignant Disease of the Large Intestine.

Mr. GORDON TAYLOR, opening the discussion, said that cancer of the alimentary tract accounted for quite half the total number of deaths which resulted from malignant disease, and that the statistics of operations done by British surgeons compared favourably with those reported from other countries. When cancer of any region of the body was under consideration, the safety of a suggested operative procedure was not the only factor to be regarded. Pending a much greater knowledge of cancer than was so far possessed, the brightest prospect of cure was still offered by ruthless surgery. Concerning methods of operating, when the growth was on the distal side of the cæcum, cæcostomy was, in most cases, the procedure of choice. A two-stage, or even a three-stage operation was a safety factor. In cases in which the colon was secondarily involved, even if partial obstruction were present, Mr. Gordon Taylor preferred to operate in stages; it was better to save a patient in two or three months than to kill him in 24 hours. Blood transfusion was particularly indicated in cases in which there was associated intestinal hæmorrhage; it was also valuable in dealing with post-operative shock. He had not had much experience of preliminary immunisation. With regard to methods of intra-abdominal anastomosis, many subjects of cancer were elderly and their vessels were already showing degenerative changes. His own custom was to avoid the use of all large crushing clamps, and, as far as possible, he chose for his incision the sides of the body or the flank close to the tumour, thus keeping clear of the middle line of the abdominal wall and the mid-stream of the abdominal cavity. He believed that the only really radical operation for a carcinomatous rectum was the abdomino-perineal method of Mr. Ernest Miles, though admittedly this procedure was of a magnitude which made many surgeons reluctant to embark on it, and sometimes consideration of safety required the performance of a less radical operation. It was with reluctance that, in more cases than he liked, he himself felt compelled to carry out what he knew to be a less perfect procedure. The statistics at St. Mark's Hospital showed 28·5 per cent. of five-year cures; and the results on a five-year basis reported from this country and from abroad showed remarkable similarity. Mr. Gordon Taylor's own end-results did not justify the optimism expressed by those practising the perineal operation alone. In an ideal subject, the division of the abdomino-perineal operation into two stages rendered it much less formidable.

The modification of technique used by him in the perineo-abdominal was that described by Mr. Grey Turner in 1920. The main portion of the operation was devoted to the perineal stage, the other, the abdominal, being brief.

In regard to radium, he asked whether it was likely that the introduction of radium tubes into the mesentery would act as a barrage against the upward spread of cancer cells which were not regarded as radio-sensitive. He considered that the greatest factor of safety in the management of cases of carcinomatous rectum was the judgment of the surgeon, who must take into consideration the age, sex, cardiovascular system, as well as the bodily configuration of the patient. The fact that so many statistics concerning cancer in the rectum and colon were based on a three-year survival seemed to indicate a spirit of pessimism. It was questionable whether one ought to advise a patient to submit himself to a serious operation if the only prospect this seemed to offer was a miserable three years of life. A mere colostomy might give a further life of from two to eight years.

DIAGNOSIS.

Dr. C. E. LAKIN raised the subject of diagnosis, basing his remarks on a case of an old woman who for nearly 20 years was in the cancer wing of Middlesex Hospital. In that wing, beds were provided for patients until, in the words of the Charter, they were either relieved by art or released by death. The release of this patient was by death. She had stricture of the rectum and a very large liver. During her stay in hospital, the diagnosis was carcinoma of the rectum, with secondary deposits in the liver; yet she lived for a very long time. At the autopsy a stricture was found just within reach of the finger from the anal margin, and an enormous mass in the liver consisting of debris and partially calcified pus. She had had an amœbic ulcer of the bowel; the lower ulcer had healed, and the supposed growth was simply a stricture, while what was supposed to be a metastasis in the liver was the large amœbic abscess from which infection had died out, and which was innocuous in the later stages. Generally speaking, the symptoms of carcinoma of the colon were not always recognisable at first. In one class of case the patient had marked anæmia when advice was first sought. In cases o carcinoma of the cardiac end of the stomach it wa sometimes difficult to say with certainty, before an elaborate examination was made, that the condition was gastric carcinoma and not pernicious anæmia Commonly, however, in gastric carcinoma, there wa a story of bowel irregularity. Another class of cas was also liable to cause confusion. For example an old woman who came up for operation was emaciated, had pyrexia, and complained of abdomina pain. She had a leucocytosis of 22,000. The diagnosis made was diverticulitis, and no operation was performed. When, later, the patient died a small annular carcinoma of the sigmoid was found and this had ulcerated posteriorly. The case had been misleading because there had been no obstruction and the patient had few symptoms except loca tenderness and fever.

Dr. BAKER spoke of precarcinomatous conditions He said that in the intestinal canal adenomatous conditions were often encountered which might result eventually in definite malignant disease. He showed microscopic sections from a case in which there was a growth of the small intestine. He drew particular attention to a raised ridge which ran round the bowel and seemed like an elongated papillomatous area. It looked like an exaggerated fold of the mucosa, and the point at which the change from the normal took place to this thickened ridge was marked. His view was that tumours started in this way, as an area in the intestine which had undergone precancerous changes, and not always as a small focus or a few cells.

Dr. P. MONKHOUSE spoke on the radium treatment of carcinoma of the rectum, remarking that he did not think the outlook in this respect was as hopeless as Mr. Gordon Taylor had indicated. In squamous-celled carcinoma of the anus, quite good results could be expected from radium, and it was, he thought, well worth while to treat such cases with radium, perhaps doing a preliminary colostomy. In rectal carcinoma the response to irradiation was very variable. Shortly before Christmas, 1930, he began to treat, with radium, a patient who had columnar-celled carcinoma, since the decision was against operation. He had inserted radium from the perineum so as to surround the growth, and the reaction of the growth to it had been very good. Generally speaking, radium treatment should not be recommended for columnar-celled carcinoma except in inoperable cases, since the reaction could not be forecast with any certainty.

Mr. W. B. GABRIEL emphasised the importance of what could be termed the old-fashioned clinical methods in diagnosing carcinoma of the colon; the tendency at the present day was to go straight to barium enemata and occult blood tests. The patient's history could give valuable information, especially a history of bowel irregularity, abdominal pain, or distension. The clinical examination should be repeated, since on one day the abdomen might be flat and apparently normal, while on another it might be somewhat distended, and possibly palpable peristalsis could be observed. After this repeated examination, occult blood tests might be done. In the barium enema examination there were many fallacies. It was a very fluid enema, and could run through a stricture which might seem impassable from an examination of the specimen. Another fallacy arose from overlapping; a distension above or below the stricture might quite obscure the stricture itself. A negative barium enema finding should never be accepted without question. With regard to cancer of the rectum, practically all such cases could be diagnosed by a combined examination with the finger and the sigmoidoscope. Cancer of the recto-sigmoidal region could not be detected by a barium enema. In the two-stage operations Mr. Gabriel did a preliminary laparotomy and colostomy under a general anæsthetic. At the second operation he gave 5 or 6 c.cm. of avertin, running it into the colon via the upper colostomy opening. The patient fell asleep, and 20 minutes later spinal anæsthesia was induced. The duration of the anæsthesia seemed to be definitely lengthened by the avertin. He had been greatly disappointed with radium, and he related cases of cancer in which radium had failed.

Dr. H. H. MILLS thought that the surgeon's judgment on whether or not an operation ought to be performed deserved as much care from him as the technical part of the operation. His impression, after a considerable experience, was that people over a certain age should be spared surgery if there was not complete obstruction. He spoke of a woman now in her ninety-fifth year, who had had an abdominal mass pressing on her venous and lymphatic system for at least eight years. Both abdomen and legs were greatly distended, she had a large liver, and she passed blood in the motions. Yet despite that she was active and happy. She had never been operated upon, and the decision to spare her surgery seemed to have been a wise one.

GRADING OF NEOPLASMS.

Mr. W. T. WARWICK recalled a patient on whom colostomy had been performed ten years previously for carcinoma of the rectum. With regard to carcinoma of the colon, a decade ago the optimistic surgeon would probably have said that he could cure a large percentage of cases; if he did not succeed, he would lay the blame on the practitioner for having allowed cases to go too far. To-day, however, the private opinion of the surgeon was much more gloomy. Carcinoma of the colon was much more malignant than was usually supposed. At Middlesex Hospital considerable importance was attached to the grading of tumours. The St. Mark's Hospital grading was an anatomical one, depending on spread through the coats of the bowel, and it was excellent so far as it went. Many sections had to be looked at in order to get satisfactory grading. Recently, however, it had been claimed that grading could be done from small portions taken from the edge of the bowel by a punch. Two workers at the Mayo Clinic had grouped 590 cancers, and had found that the percentage of cases in which metastases occurred increased in direct proportion to the grade of malignancy. There were four grades of increasing malignancy. In the first were 103 cases; in the second, 293; in the third, 139; in the fourth, 52. Grades 2 and 3, the intermediate groups, were by far the most common in cancer of the rectum. The percentage of patients who died after a fixed interval rose, in the four grades, as follows: 44, 62, 75, and 86.

Whether it was possible to do anything to help overcome the infection of the growth and to make the secondary operation less hazardous by means of intraperitoneal vaccination was a question which could not yet be answered. Certainly, however, drainage of the bowel and the use of intravenous hypertonic salines and glucose did help considerably to improve the patient's condition. Blood transfusion completed the pre-operative measures. The post-operative measures should include intravenous glucose, or intravenous or subcutaneous water and saline, in order to rest the anastomosis as much as possible. In a large number of cases the cæcostomy worked to a minimal extent after the excision of the growth combined with anastomosis. The bowel should be rested after operation by giving as much fluid as possible intravenously or subcutaneously, and combining it with glucose.

Dr. GERALD SLOT remarked that many patients, in hospital at any rate, gave a history suggestive of neoplasm. Further investigation, for example, barium enemas—which were not always possible—gave only inconclusive results, and the question arose what further means should be taken to make an accurate diagnosis. It had been found that, when only small growths were in the colon, the whole of the under surface of the liver was apt to be studded with even smaller growths. Metastasis in such cases was probably far more prevalent than it was commonly supposed to be. The treatment of inoperable cases with heavy metal salts—cuprase and selenium, for instance—had to be considered. Dr. Slot had seen two cases treated in this way in England, though both died eventually, the treatment afforded considerable relief.

Dr. STEWART WEBB said that a large proportion of intestinal growths were detectable, but too often the technique employed was faulty. Often the enema given was so bulky that the walls were distended. Growths on the right side of the colon were better detected by giving a barium meal.

The CHAIRMAN summarised the discussion. He said that private patients who could not be sent to hospital and could not afford expensive nursing homes were those who were seriously inconvenienced by the expense and the difficulty of securing the more elaborate means of diagnosis. It would be well if the profession could devise means for overcoming this difficulty.

Mr. GORDON TAYLOR, in reply, related a number of cases of malignant disease in which radium or X rays were unavailing, and said it was significant that the authorities in charge of the Radium Clinic in Paris were adverse to the treatment of any kind of carcinoma of the rectum by that means.

ROYAL SOCIETY OF MEDICINE.

SECTION OF NEUROLOGY.

AT a meeting of this Section held on Jan. 8th, the chair being taken by Mr. LESLIE PATON, the President, a paper on the

Ætiology of Disseminated Sclerosis

was read by Dr. E. A. CARMICHAEL. He discussed the evidence for the presence of a virus (*Spherula insularis*) under the four headings of the Lange gold-sol curve, the lævulose-tolerance test, the variation in the pH of cultures, and the microscopic appearance of cultures.

Only undoubted cases of disseminated sclerosis had been examined, he said, and they had been grouped into acute, progressive, and stationary. The gold-sol solution had been made according to the method of Mellanby and Davies, and only samples giving a typical paretic curve with untreated cases of general paralysis had been used. The character of the curve had been found to be in no way associated with the stage of the disease, and in only 31·9 per cent. of the 94 cases had curves of three or over been obtained. Apparently, therefore, the workers at the Westminster Hospital who had obtained 54 per cent. of curves over three might have been using a too sensitive solution.

The lævulose used had contained about 5 per cent. impurity and the estimates had been made by Hagedorn's method. Only 6 out of 28 cases had shown a rise of over 30 mg. in the blood-sugar after the ingestion of 50 g. of lævulose. The workers at the Westminster Hospital had suggested that rises of 70 mg. and over occurred in 70 per cent.; possibly they had used less pure lævulose or else arsenical treatment might have disturbed the liver function.

EXAMINATION OF CULTURES.

Great care had been paid to the pH determinations, which had been performed by the closed cell method with colorimetric methods as confirmation. Corrections had been made for temperature, and the investigator had not known the clinical data or nature of the case until after he had concluded the estimation. The Hartley's broth had been obtained from the same source as that used at the Westminster Hospital and the serum had come from volunteer students of St. Bartholomew's. The proportions of serum, broth, and cerebro-spinal fluid had been those recommended by Miss K. Chevassut. The pH value of serum had been found to differ in various samples, so that the addition of serum to broth in constant proportions would give different pH values to the resulting mixture. Moreover, if the ratio of broth to serum was altered, the pH value of the resulting mixture varied. In order to obtain a mixture with a constant pH value of 7·5 to 7·6 the mixture had been titrated with decinormal acid or alkali, and also a number of untitrated mixtures of various pH values were used. It had been stated in the work from the Westminster Hospital that a mixture of broth and serum kept its pH value of 7·6 over a period of days, or else became slightly acid. It had been found, however, that when fresh serum was used the mixture invariably became alkaline, presumably on account of the loss of carbon dioxide. Cerebro-spinal fluid from a number of cases not suffering from disease of the central nervous system had been added to the broth and serum mixture, and in every case the pH had risen to the alkaline side, reaching a level of eight or more. When the cerebro-spinal fluid had been taken from cases of disseminated sclerosis the same result had been obtained. Thus in 19 cases, of all three types, no confirmation of the shift to the acid side had been obtained. No matter how the mixture of serum and broth had been prepared and no matter what the source of the cerebro-spinal fluid, the resulting mixture had always become more alkaline. An investigation into the quantity of carbon dioxide had shown that the increased alkalinity was due to a very considerable loss of this gas; if it were retained to some extent by culturing under paraffin the shift to the alkaline side had become less evident, and if it were replaced by putting the mixture in a partial pressure of carbon dioxide equal to that of the alveolar air the pH value had moved to the acid side, returning to the alkaline side after exposure to the air. As no precautions had been adopted at the Westminster Hospital to avoid the loss of carbon dioxide it was impossible to explain or to repeat their figures using aerobic methods of cultivation.

The microscopic picture of 19 cultures of disseminated sclerosis fluid differed in no way from the picture of normal fluids or of uninoculated material and no distinctive spherules had been found. His experiments, therefore, Dr. Carmichael concluded, failed to substantiate the work from the Westminster Hospital claiming the presence of a virus in cultures of cerebro-spinal fluid from cases of disseminated sclerosis. Miss Chevassut had been supplied with 32 unlabelled specimens of cerebro-spinal fluid, of which 14 came from cases of disseminated sclerosis and 18 from other sources. She failed to find the spherula in any of the former, but demonstrated it in one of the controls, a fluid from a case of chorea.

The Case for the Virus.

Sir JAMES PURVES-STEWART welcomed criticisms of Miss Chevassut's work, but thought that many of Dr. Carmichael's results which were at variance with hers were due to the use of different methods. The difference in the gold curve seemed more apparent than real. A positive gold curve did not necessarily prove the existence of a living virus. It was probably a mere concomitant phenomenon, the result of some toxin produced by the causal organism. Deficiency of metabolic and antitoxic liver functions indicated a toxic factor, but lævulose-tolerance tests by themselves were of little value as indicating deficiency of liver function unless accompanied by positive indican and glycuronic acid tests in the urine. It was not surprising that the two workers had obtained different pH results, since they had used different types of electrode; the experiments were not comparable. Dr. Carmichael had obtained negative cultures from 19 cases, but Miss Chevassut had examined 410 cases with a high percentage of positive results; Smith and Ransome[1] had secured positive cultures in

---

[1] THE LANCET, 1930, ii., 901.

9 out of 11 cases, and Zerkowitz, of Budapest, had secured positive cultures in 26 out of 28 cases. The problem called for further research.

Miss **KATHLEEN CHEVASSUT** said that the gold curve and lævulose-tolerance test had never been claimed as evidence for a virus. She had merely concluded that in disseminated sclerosis there was deficiency in the antitoxic and metabolic functions of the liver and that there was, therefore, probably a toxic factor. In her original paper she had stated that the precipitation of colloidal gold could not possibly be related directly to the presence of a virus, but had suggested that the factor might be some toxin or other product and that this possibility would be further investigated. She criticised Dr. Carmichael's method of preparing a gold solution and said that hers had been prepared by the original method of Lange. He had misunderstood her remarks on the gold curve; the point had been that in disseminated sclerosis precipitation almost invariably occurred first in the fourth tube—i.e., a dilution of 1–80—and that this tube usually showed the maximum precipitation. She had added that in any case the degree of precipitation was usually not greater than that indicated by the figures 3 or 4. Dr. Carmichael suggested that the lævulose might have been impure; it had been the purest obtainable on the market and the same as that used by Dr. Carmichael. A certain number of tests with galactose had confirmed the lævulose-tolerance test, and Dr. A. F. Hurst had further confirmed her results.[3] It was the correlation of three tests—the lævulose-tolerance test, the indican test, and the glycuronic acid test—which had led to the conclusion that the detoxicating power of the liver was deficient.

Experiments dealing with pH values were not proof of a living virus; she could not, therefore, agree that they were of more value than microscopical observations. The obvious fallacy in Dr. Carmichael's work was that he was attempting to measure the reaction of cultures without knowing whether they were cultures or not. Dr. Carmichael had discarded the hydrogen electrode method because it removed easily dissociated carbon dioxide from the mixture; this was the precise reason for which she had adopted it. It was obvious that carbon dioxide was bound to be lost, and the best method had seemed to be one in which this variable factor was removed. Then the experimenter was left with one factor only—viz., any variation in hydrogen-ion concentration induced by something specific in the cultures themselves. A little consideration would show that the prevention of loss of carbon dioxide would defeat the object of making the cultures, since the conditions of growth of an aerobic virus would not be fulfilled. Hartley's broth was a well-buffered medium, and this buffering capacity must be recognised if the experiments were to be understood. By Dr. Carmichael's method the shift to the alkaline side was made inevitable, and this would mask the slight change to the acid side, even if he were dealing with positive cultures, since change of reaction only occurs in an active growing culture. In her early work negative results had been so uniform as to be completely discouraging, and positive results had only been obtained when the somewhat difficult technique had been rendered much more perfect and the microscopic appearance in cultures had been established as the basis for pH experiments. Even in her early work she held the opinion that the occasional change of reaction demonstrable was valueless unless it could be correlated with either a microscopical appearance or some other property inherent in the culture. Dr. Carmichael had examined 19 cultures of disseminated sclerosis but of these only 11 fulfilled the condition laid down in her paper—namely, that the fluid must be cultured immediately after withdrawal.

DISCUSSION.

Dr. **J. H. MARRACK** said that it would be absolutely impossible to wash out all the carbon dioxide in a reasonable time; so long as the pH remained at 7·5 an appreciable amount of the carbon dioxide was free. Therefore experiments with the bubbling hydrogen electrode showed nothing. They did not show the pH of the fluid at the beginning or when all the free carbon dioxide had been washed out, but at some intermediate stage which varied with the conditions of the experiment.

Mr. **J. E. BARNARD** said he had examined eight of Dr. Carmichael's cultures and had failed to find anything unusual. He had seen something in Miss Chevassut's cultures that he had never seen under other circumstances, but she had done a very large number of experiments and he had seen a very small proportion of them.

Mrs. **TOOKEY KERRIDGE** spoke of the great difficulties of working with the hydrogen electrode, and said that Dr. Carmichael's method was the one most likely to give consistent results, because he would tend to lose a certain definite amount of carbon dioxide. Nevertheless, the errors seemed to go the wrong way; the pH would be expected to be more alkaline in Miss Chevassut's method. Dr. Carmichael's results did not suggest at all why Miss Chevassut's results should have shown an acid change.

Dr. **J. G. GREENFIELD** said that undoubted cases of sclerosis sometimes yielded normal cerebro-spinal fluid in the absence of any kind of treatment.

Dr. **CARMICHAEL**, in reply, said he had never met "the germ" that would give a pH reaction of 6·0, as Miss Chevassut had stated, and therefore he could not explain her finding.

Dr. J. **PURDON MARTIN** read a paper on

Chronic Subdural Hæmatoma.

He defined subdural hæmatoma as an encysted collection of blood between the dura and the arachnoid, and showed a specimen removed from a man of 58 who had been well until five weeks before his death, when he had woken up one night with an attack of vomiting. This had continued for several days with intermittent severe frontal headache. Thereafter he had gradually deteriorated mentally and physically. The relatives, when questioned, had said that he had fallen when getting off an omnibus about a year earlier but had not apparently sustained any injury.

These cases were uncommon but hardly rare, said Dr. Martin, and he would refer to six cases, three from his own experience during the last year. The pathology was puzzling; the blood probably came from a small dural vein torn by sudden dislocation of the brain within the cranium. The hæmatoma enlarged gradually, and by the time it caused symptoms usually extended over the frontal or parietal lobe. It was bilateral in about 40 per cent. of cases and some of the blood always remained fluid, probably being defibrinated by the pulsation of the brain. It was enclosed by two fibrous membranes containing numerous blood vessels and blood spaces containing blood from the general circulation, but no doubt contributing at times to the hæmatoma. As it enlarged the brain eventually became compressed or collapsed.

Five-sixths of the cases were men, [illegible] was nearly always a history [illegible] ther causes of vascular degeneration also played a part. The condition was much commoner after 40 and in younger subjects the trauma was considerable, whereas in older men it might be negligible. Alcohol might have a subsidiary place in the causation. The latent period seemed to be shorter the more severe the trauma. The first symptoms were general: drowsiness, mental change and headache, leading gradually to coma. Focal symptoms, if present at all, were late and partial. Ocular signs were common. Diagnosis must be made without a history of trauma. Drowsiness might also be seen in cases of frontal tumour, but was seldom so variable or so rapid in its progress as in subdural hæmatoma. There was no general intracranial pressure, so that lumbar puncture would not reveal any abnormality. Papillœdema, however, had been reported quite frequently, and vomiting was not uncommon. Sensory defects were less common than motor. In about 10 per cent. of cases the urine contained albumin. If the condition was suspected, an exploratory trephining should be done; treatment was an evacuation of the hæmatoma and was usually successful at once. Occasionally the hæmatoma filled up again.

---

[3] THE LANCET, 1930, i., 659.

Dr. C. P. **Symonds** spoke of the difficulties of diagnosis and the need for exploratory operation in all suspicious cases. In three of his cases the patients had sought advice as much for the focal signs as for the drowsiness and headache. The ruptured vein was often one of the small vessels running from the brain to the superior longitudinal sinus. In two patients the earliest symptom had been shuffling and dragging of one leg with slow spastic paralysis and slight paralysis of the arm, corresponding with bleeding from such a vein. One of his cases had had flakes of fibrin in the cerebro-spinal fluid.

SECTION OF PSYCHIATRY.

At a meeting of this Section on Jan. 13th, Dr. S. A. **Kinnier Wilson**, the President, took the chair, and Dr. **Alfred Adler** (Vienna) spoke on

The Structure of Neurosis.

The collection of experience, he said, did not make science; it was necessary to find the underlying principles, and these must be proved by logic, common sense, and experience. The first crucial problem was how mind experienced body; the new-born child was not rightly related with his body. The second crucial point was how experience influenced mind. The mind could not automatically develop all that it inherited because of the opposition of the environment. It was impossible to know what was an inherited mental ability, because in every step the child took there was interference—the interference of the mother; every attitude and behaviour of the mother impressed the child differently. It was possible that the child was free to respond as he wished to the impressions of the external world; it was impossible to predict how they would work. It was worth while to encourage good influences, as it was probable that the child would make a better response to good than to bad influences. The child was at the beginning of life, had possibilities that we could not estimate, and an active power in his own way.

Individual psychology, therefore, strongly emphasised the value of education. The idea of education had become less important owing to the stress laid on inheritance. Environmental influences were known to have different results, however much they were standardised, and therefore little credit could be given to a system that considered environment alone. After some time in a given environment a child found a way of life, with a definite direction It was impossible to consider movement without considering the goal; the child must have a goal. Adaptation was a useful word in psychology, and it was true that every individual had to adapt. But beyond each person's adaptation lay a different goal. Every human being was striving to overcome difficulties. Without trusting too much to metaphorical comparisons, this striving could be understood from a consideration of bodily development, which was also striving for a final form. This was the view that individual psychology had introduced under the term "finalism." Movement could only be understood by an understanding of the goal. The child, with his active power, built up form—a style of life—and this style was the creation of each child. Because each child created, we could not rely on a system which depended on causes and effects. The child was in the realm of uncertainty and guesswork, and in the many variations seen on each point the psychologist must look for individual development, and therefore individual psychology. The child's goal was how to conquer, how to become superior, to strive for completion, to adapt. After four or five years he had found this goal, had a certain prototype, a scheme of perception, an individual perspective, a certain degree of social interest towards others, and a certain degree of courage. He performed his tasks in his own way, assimilated with his own organs, digested with his own ability, and effected in his own way. No two individuals were identical in their conceptions, their perceptions, their feelings, their actions, or their thoughts; each of these belonged to the style of life created by the child.

THE NEED FOR SOCIAL INTEREST AND COÖPERATION.

Human beings were social beings; everybody knew this, but there were great differences in the expression of the knowledge. Social interest was the key of the psyche and of psychology. This could be understood from many points of view, perhaps the most convincing being that social interest was involved in every activity of life; the child had to coöperate with the mother from its birth. There must be somebody with whom he coöperated. All psychological functions were important from the point of view of this coöperation. The child, coöperating by means of his eyes, perceived and understood the world much better. In all life's failures the right degree of coöperation, of social interest was lacking. It was not a personal matter; all social failures had a private intelligence. To understand properly meant to have been told by the whole of experience that this was the way others would understand. The child thus brought up wanted to coöperate, and did not seek the pleasure principle alone. This ability to coöperate, this social interest, could and must be taught; of course there was an hereditary ability to develop it, but not a very deep one. It must be taught like history or geography. All the problems of life would need it, from the kindergarten onwards. The child not properly trained had a dark, uneasy feeling that he could not solve his problems, and behaved like a spoiled child that wanted to exclude everybody, like a man who could not pay.

TENSION PRODUCING SYMPTOMS.

Therefore a tension arose and vibrations spread all through the body; these appeared most at "weak spots" and caused diagnostic symptoms—a functional neurosis. His suffering spoke; it was a dialect of the organs. Often the organs affected had some inherited or familial abnormality and often the endocrine function was altered. Fear might be shown by erection of hairs, disturbances of the bladder, quickened breathing, palpitation of the heart, or irritation of the sexual organs; but in each case there was a meaning to the symptoms. The patient in fear or tension excluded things from his life, but always suffered this tension, this striving for superiority, and so in social life began to use his symptoms. In practice there was no distinction between thought, feeling, and action, and the tension might arouse primarily thoughts or primarily feelings. The psychiatrist must always find the whole line leading to action, and understand how the patient had created a new way in which he could be adapted and could express his inferiority complex while finding a superiority. He was no better adapted socially, but he no longer felt himself falling down. In the structure of every neurosis would be found an attempt to become dependent on another and to make that other dependent on him. He had to prove that he must take this way, though he would prefer the normal way; hence the inevitable phrase of the neurotic: "Yes—but—." The neurosis could be traced back towards mistakes of the mother, perhaps, who had taught the child to build up his life in a dependent manner. All the social failures showed this lack of social interest and fear of coöperation. Confronted with the need for coöperation they felt as if they stood before an abyss Therefore, these people must never be pushed; they did not seek their solution as normal men but with a conviction of failure.

Neurotics had a peculiar degree of social interest; they did not want directly to hurt other persons but to make them dependent. Invariably they had been pampered dependent children, but this history did not appear until they were tested. Every case-history should, therefore, describe the situation in which the symptom had appeared. Love and marriage, for instance, immediately tested the individual's ability to coöperate, to build up a new future, and care for the partner. All neurotics were sensitive, because they were living in a world to which they were not adapted, and they always felt enmity. This sensitiveness was also found among problem children, suicides, and criminals. All failures, too, were always impatient; they had not the self-confidence to wait. Nevertheless, each neurotic differed from all others; each had created a masterpiece of art. Each expressed himself in an individual style of life and reacted in the same way throughout his life. This agreement in the whole life-style could be used for treatment, and also for prevention. If parents could be taught to prevent, that would be the best way, but those who needed it the most never saw the psychiatrist. Prevention could, however, be started at school, if the teachers looked out for faulty styles of life and shrinking from social interest. When the patient was adult, treatment lay in convincing him of his lack of coöperation, training him to coöperate first with the doctor, who replaced the mother, and then with others.

DISCUSSION.

Dr. R. L. WORRALL asked what was to be said to the suicide or criminal who ascribed his act to poverty.

Dr. ADLER replied that this could not be the real reason, for many poor people did not commit crime. These people lacked energy to attack someone else but suicide was a form of attack, of revenge. The whole style of life must be changed. The formula of the neurotic was "Yes, but—"; of the criminal "No"; the latter did not want to go the normal way. The neurotic could not form a gang; there could not be a society of persons suffering from anxiety, but the criminal had enough social interest to join others of his own way of life.

Dr. PARKES WEBER compared Dr. Adler's teaching to the old saying "know thyself." Everybody ought to recognise their inferiorities and be contented with those they could not remedy. He thought the English system of boys' education last century had done much to obviate the results of inferiority; public school boys had been taught to find their level. He asked what happened when a man could not react normally because of some purely physical disability—e.g., epidemic encephalitis, which he thought was as well explained by the theory of inferiority as by any other, the organ affected being the organ of the mind.

Dr. E. B. STRAUSS asked which of Kretschmer's two types was the normal temperament.—Dr. ADLER pointed out that there were mixtures and geniuses and failures of both types; it depended in each type on the amount of social interest preserved. —Dr. A. F. DOBBIE-BATEMAN asked at what stage the semi-sanity of all of us became neurosis.—Dr. ADLER replied that no general rules could be laid down; all individuals differed, but the degree of social interest was the best guide to the amount of neurosis.

SECTION OF OPHTHALMOLOGY.

AT a meeting of this Section on Jan. 9th, with Mr. ELMORE BREWERTON, the President, in the chair, a paper on

Cataract from Exposure to X Rays

was read by Mr. R. FOSTER MOORE. It concerned a patient in whom cataract was produced by exposure of the eyes to heavy doses of X rays during the treatment of sycosis on the face.

He was a man aged 28, and was seen by dermatologists because of severe sycosis of scalp, face, and neck, of three years' duration during which he had been to several hospitals, the treatment having included X rays, which the patient said made him worse. In this last treatment, because of certain risks attending X ray treatment, a signed statement was obtained from the man expressing his willingness to have the treatment. The disease affected the eyelashes as well as other parts of the face. The treatment lasted from February to June, 1927, and the total given was 12 Sabouraud doses. It completely cured the sycosis, and there had been no recurrence, but telangiectases gradually appeared, and had remained, apparently unchanged, until the present time.

In November, 1929, his sight began to fail, his acuity in March of that year being 6/12 in each eye; but since Christmas of that year he had been unable to read a book. In June, 1930, when Mr. Foster Moore saw him, the vision was only 6/60 in each eye, and there was a plaque-like opacity in the posterior cortex of each lens, while bordering this was a powdery opacity. The fundi were normal.

Last May Mr. Moore needled the right cataract, and in October Mr. J. G. Milner needled the other. The progress was uneventful, and after capsulotomy the acuity in the right was 6/6; absorption of the left was not yet complete, but was running a normal course. Most of the opacity was in the lens substance, adjacent to the posterior capsule.

The first case of this kind reported, said Mr. Moore, was in 1909 by Mr. Leslie Paton. In all recorded instances the dose of X rays had been heavy, and efficient protection of the eyes had not been possible. He commented on the length of time which elapsed between the exposures and the affection of the lens, two and a half years in the present case. He thought that, even when the eyelids needed treatment, a nicely adjusted shield would give the eye the necessary protection.

REVIEWS AND NOTICES OF BOOKS

Burns: Types, Pathology and Management.

By GEORGE T. PACK, B.S., M.D., Fellow of the Memorial Hospital, New York City; and A. HOBSON DAVIS, B.S., M.D. London: J. B. Lippincott Company. 1930. Pp. 364. 25s.

THE advent of tannic acid technique has doubtless stimulated much of the interest shown in America in recent years in the pathology and treatment of burns. Whether or not this new form of local treatment is epoch-making, as this and other transatlantic volumes declare, remains to be proved. A comprehensive and up-to-date survey of the subject is here presented in three sections; the facts about burns, the management of burns, and burns by specific agents. Chapters on the blood and urine changes, the complications, and on burns due to electricity, sun, radium, and war gases are particularly valuable. The numerous theories of the pathology and the equally numerous forms of treatment are all detailed; though the impartiality shown is praiseworthy, the book would have been more interesting if the authors had indicated their own preferences. But the insistence on the importance of primary shock, which has been belittled by some as a common cause of death, and on the necessity for the administration of fluids in toxæmia, a matter too often neglected, show that they are alive to the essentials; their views are basically sound, and this outweighs a lack of guidance among the multitudinous forms of local treatment. The sections upon care of the burn with a view to the prevention and limitation of deformity are admirable. A comprehensive bibliography follows each chapter.

Physiotherapy: Its Principles and Practice.

By F. HOWARD HUMPHRIS, M.D. Brux., M.R.C.S. Eng., D.M.R. & E. Camb., Hon. Consultant X Ray Physician to Christ's Hospital; and R. E. STUART-WEBB, M.B., M.R.C.S. With contributions by FRANK ROMER, M.R.C.S., A. E. HAYWARD PINCH, F.R.C.S., M.R.C.P., and A. GORDON WATSON, M.D. London: Jonathan Cape. 1930. Pp. 384. 15s.

ALL the important branches of physical medicine are considered in this book. The major portion, comprising about one-half of the volume, deals with the *principles* of electrotherapy, radiant heat, phototherapy, ultra-violet ray therapy, X ray therapy, radium therapy, massage and manipulation, spa treatment, and certain miscellaneous therapeutic agents—viz., melted wax, foam, carbon dioxide snow, and mechanical vibration. The sections on radium therapy, massage and manipulation, and spa treatment are by Mr. Hayward Pinch, Mr. Frank Romer, and Dr. A. Gordon Watson, respectively. The treatment of various diseases by physical methods is dealt with in a second part of the book, which comprises rather less than one-half. In this part the diseases of the different system of the body that are suitable for physical treatment are considered, and the authors describe the form, or forms, of treatment which they consider most suitable. This part is followed by a 34-page glossary of physical and medico-physical terms, and a short index.

In a book of this size it is manifestly impossible to devote to each branch of physical medicine the attention which its importance deserves. This applies more particularly to that part of the book dealing with *principles*, where 76 pages are devoted to electrotherapy and only eight to X ray therapy. It is likely, however, that there are many general practitioners of medicine who desire to acquire some information on the nature of radium therapy, mechanotherapy, hydrotherapy, and other forms of physical treatment without reading the text-books dealing with the subjects separately. A perusal of these text-books shows that there is considerable overlapping of the therapeutic fields of different forms of physical treatment, and the reader is left in doubt as to the treatment which he should prescribe. The authors of the present volume select and recommend the treatment which they consider the best. It is to be noted that electrical currents are most often prescribed, particularly those derived from the static machine. Dr. Humphris is a well-known exponent of the value of treatment by static electricity. Considerable importance is attached to the red and infra-red rays. It is said that the latter have a relatively high power of penetration, and that those which pass through water will pass through 3 cm. of body tissue before being absorbed. The meaning of the statement that "human heat may be said to be the absorption of infra-red rays in the body" is not quite clear. A description is given of a method devised by Dr. C. A. Robinson for subjecting the male urethra to diathermy in cases of gonorrhœa. It is not stated, however, that Dr. Robinson never attributed any value to diathermy in the treatment of gonococcal urethritis in men, and there is no reference to his work when the treatment of salpingitis is described. The results of his pioneer investigations on the use of diathermy in salpingitis were communicated to the Section of Electrotherapeutics of the Royal Society of Medicine over two years ago. There is no mention of his work on the treatment of pneumonia by diathermy in the pages dealing with that subject although by far the largest amount of work yet done in this country has been conducted by him.

The general practitioner will find much of interest in this book and some useful information will be gained in regard to the selection of forms of physical treatment for different diseases. It is written in an easy and colloquial style, and there are amusin passages. Writing on the treatment of overstraine voice by means of the "high-frequency vacuu current from the static machine," it is said that "th treatment has proved to be of great benefit to all sor and conditions of men and women, from opera singe to political speakers and politicians of all parties."

Téléradiographie Stéréoradiographie.

By L. DIOCLES, Chef du Laboratoire de radiologi de la Clinique médicale de l'Hôtel-Dieu. Paris Masson et Cie. 1930. Pp. 215. Fr.30.

IN this book M. Diocles gives an historical survey and a very detailed account of the principles of stereoscopy, and makes a strong plea for the extended use of stereoscopic radiography and telestereoscopy. He claims great advantages for this method, and maintains that the only reason for its neglect is the report of disappointing results which were due to faulty technique. He describes his own technique in detail and recommends stereoscopic radiography for all parts of the body. If some of his claims for the method seem rather too enthusiastic, he supplies much interesting information on stereoscopic work, including chapters on making reduced stereoscopic prints and stereoscopic projection. The book will be useful, because it contains much collected information which it would be difficult to find from other sources.

ud that the addition of
n cases of disseminated

sed the reaction to become at first more
ıen to return to the alkaline side. In
g the reaction she used a bubbling
electrode. Dr. Carmichael states that
ade up according to Miss Chevassut's
s *do not yield a standard reaction, that the*
of the medium does not remain unchanged,
comes gradually more alkaline, and that
curs equally when cerebro-spinal fluid from
of disseminated sclerosis and when control
are added to the medium. In the determina-
of reaction Dr. Carmichael used a closed cell
rode. There is thus an apparent discrepancy
veen Miss Chevassut's and Dr. Carmichael's
ults. As Sir James Purves-Stewart pointed out,
ey were using different methods of determining
ıe reaction of their mixtures and therefore their
esults are not comparable. Dr. Carmichael
abandoned Miss Chevassut's method because he
found that it led to frothing of the mixture. Miss Chevassut in reply said that she took precautions to prevent frothing. It is possible that the bubbling hydrogen electrode in Miss Chevassut's hands *yielded more constant results than in* Dr. Carmichael's. Dr. J. R. Marrack condemned it as unreliable, but Mrs. Tookey Kerridge pointed out that the tendency of this instrument would be to render the mixture more alkaline, whereas Miss Chevassut's positive results consisted of a change to the acid side and were therefore inexplicable merely as products of faulty technique. It seems impossible to judge from verbal discussion the relative merits of the two techniques, for much may depend upon the precise way in which a worker carries out an operation. We cannot at present rule out the possibility that the difference between *Miss Chevassut's and Dr. Carmichael's results may* be due to differences of method. It is unfortunate that Dr. Carmichael did not persevere with Miss Chevassut's method as well as with his own in order to ascertain the results yielded by the two methods on the same material in the hands of one observer.

Dr. Carmichael failed equally to confirm Miss Chevassut's findings of the *Spherula insularis* in *cultures of the cerebro-spinal fluid from 19 cases of* disseminated sclerosis. Sir James Purves-Stewart in reply pointed out that since Miss Chevassut's original paper was published she had examined 234 more specimens with positive results in 89 per cent., and that Smith and Ransome had been successful 9 times out of 11 and a worker in Budapest 26 times out of 28. We thus encounter a further discrepancy of *which no one present at* the meeting offered any explanation. Dr. Carmichael finally explained that Miss Chevassut had been supplied with 32 unlabelled specimens of cerebro-spinal fluid; 14 of these came from cases of disseminated sclerosis, and she failed to demonstrate the spherula in any of them; she found it, however, in one of the control specimens which came from a case of chorea. *This may be a crucial test, for on* her own showing it should be possible to detect the fluid from a case of disseminated sclerosis by the presence of the spherula 9 times out of 10. It may be suggested that in the past the conditions of the test have been unsatisfactory. It is of

---

:0, 1., 552, 560, 612.

urgent importance that Miss Chevassut should accept Dr. Carmichael's invitation, more than once repeated, to carry out these tests under her own conditions at the National Hospital. It is highly unsatisfactory that three years after Sir James Purves-Stewart began to treat patients with vaccines of the *Spherula insularis,* and ten months after the discovery of the organism was announced, this simple issue should still be undetermined. Also it would seem an elementary step in the investigation of a supposed organism that living cultures should be supplied to the investigator for examination. That such an obvious course has not been taken calls for explanation. The responsibility of those who claim to make discoveries in medicine extends beyond the therapeutic applications of their work. They owe it to society to court refutation by putting all their resources at the disposal of their critics.

In conclusion, we must reiterate our opinion, first expressed last March, that the bodies described by Miss *Chevassut, even if we concede their* characteristics to the full extent claimed by her, have not yet been demonstrated to be the cause of disseminated sclerosis. In Dr. HANS ZINSSER'S[2] words, "We believe that the only possible way of being sure at the present time that a filtrable virus is present in supposed cultures is demonstrable virulence, and that to assume that any ultramicroscopic appearances in hypothetical cultures are the virus and then base immunological or therapeutic conclusions on the presence or absence of these appearances is merely creating a circle of reasoning that brings us no nearer solutions."

PROFESSIONAL DISCIPLINE IN PANEL PRACTICE.

TWENTY years ago this country adopted a system of national health insurance which took for granted the coöperation of the general practitioner. He undertook his share in the new national medical service not without certain misgivings, and it would be idle to pretend that time and experience have persuaded him that the system is now perfect. We are not here concerned with the political principles or prejudices which may emerge in a discussion of social services progressively provided by the State. Nor are we now considering the limitations upon medical treatment and clinical efficiency under the Act. We desire simply to refer to certain disabilities of professional control to which the general practitioner is exposed in health insurance work as contrasted with private practice. This is one of the points taken in the valuably constructive proceedings and report lately published by the National Health Insurance Acts Section of the Paddington Medical Society. Some of the recommendations from that report are set out on p. 166.

The medical practitioner has to comply with two standards—namely, that of the general law of the land and that of the rules of conduct peculiar to his profession. Failure in the latter respect may be hardly less serious for him than breach of the general law. Service under the national health insurance system sets him yet a third standard, a standard of skill, application, and conduct which is different from—and tends to be higher than—the standard applicable to the non-panel practitioner. Not only is this standard different, but it is differently enforced. General jurisdiction over medical practitioners is wisely entrusted to the General Medical Council under an arrangement with which the public, the law-courts, and the medical profession itself are substantially content. The special jurisdiction over the panel practitioner, on the other hand, is partly popular and partly departmental. The insured patient, reasonable enough in most cases, is sometimes ignorant, captious, and exacting. When he makes a complaint he is in a privileged position. The insurance committees which handle these complaints may contain a quite inadequate proportion of professional members. The rules to be applied—for instance the basis on which excessive prescribing is calculated —are sometimes wooden and stupid. Finally, the Minister's ultimate decision, vital to the practitioner, cannot fail to appear arbitrary so long as no appeal to the law-courts is permitted, though the actions of the Ministry have always been taken with full sympathy for the profession as a whole. Since both panel practitioner and panel patient would prefer that their relationship should more closely approximate to that which obtains in private practice, one simple reform would be to remove the special disciplinary control to which the panel doctor is subjected. Allegations of improper certification are often made against the pane doctor. This is an issue with which the Genera Medical Council has always dealt in controlling general practice; why should it not deal with th same issue when the complaint arises in pane practice?

But the General Medical Council cannot be th recipients of all and every allegation against pane practitioners, nor are the decisions of that bod more open to appeal than those of the Ministe of Health. The difficulties implied by the intro duction of the law-courts in defence of aggrieve practitioners is obvious, but this may be eventuall found the only course to ensure justice.

RADIUM AND RESEARCH.

THE present position of radium therapy has been reached by processes typical of this country. I is the individual effort, which by its persistence brings into play the collective effort, that accounts for the widespread recognition of radium as a therapeutic agent. A few there were who, before the war, recognised that radium was of value in medicine, but the measure of its value could only be taken by people getting to work on it. The Medical Research Council were well aware of this situation when they started about 10 years ago their scheme of research into the medical uses of radium, really its use in cancer. A retrospect of this research, obtained by studying the Council's annual radium reports, leaves the reader in no doubt about the value of radium in the treatment of several varieties of cancer; it will also give him a good idea of the development of technique over this period. These reports have led to the recognition by almost every medical faculty in the country of the value of radium therapy as we now know it. But there are good reasons for believing that the scope of this therapy will be widened in the future. In the first place the country may be said to be fairly well off in its supplies. About two years ago the Committee of Civil Research, which went into the matter carefully, showed how badly supplies were needed everywhere, London being relatively the best off. Since then King Edward's Hospital Fund has distributed nearly 10 grammes of radium among twenty-four London hospitals (see p. 159) and something similar has been done for the country at large by the Radium Commission. Up to the end of the year just completed a total of over 20 grammes of radium has been delivered by the Radium Belge to the Commission, and has been tested by the National Physical Laboratory; 15 grammes of this have been sent to the various National Radium Centres and are in full clinical use there.

---

[2] Zinsser, H.: Jour. Nerv. and Ment. Dis., 1930, lxxii., 655.

The cause of research in this subject has been helped by the governing bodies of individual institutions, by the Medical Research Council, and by grants in aid from the British Empire Cancer Campaign. The four big organisations named represent an enormous degree of support for the advancement, not merely of radium therapy, but of radiology generally; but if we are honest we must admit that in one respect we are not in a position to take full advantage of the potential help that here exists. In spite of the widespread medical uses of X rays and radium, the fact remains that there are few radiological laboratories in the country where research on the medical uses of these agents can be carried out. Opportunities and inducements for those wishing to do this kind of research are extremely limited. On the radiological side the lines of research being opened out are, broadly speaking, physical and biological, and their pursuit can best be undertaken in a radiological laboratory with suitably chosen personnel. It is not too much to hope that in the near future hospitals and other similar institutions will provide facilities of this kind. There is still an uncomfortable amount of truth in the gibe that the whole of radiology in its radiotherapeutic aspect lacks scientific basis and rests largely on an empirical footing. Perhaps it would be true to say that, although the selective action of these rays is a duly accredited scientific fact, the essential action of the rays on living forms is still a matter of conjecture. To admit this is to see the need for more research on such fundamental matters, and it may well be that the physiologist and biologist are just as likely to make contributions to such an issue as is the pathologist. There are dangers in widening, just as there are in narrowing, the scope of research; but it can hardly be doubted that for the development of radiology safety lies in the wider view. Far more knowledge is needed of the ways in which radium and X rays can affect the vital processes of the normal body before their effect on pathological processes can be rightly conjectured or rationally interpreted; such knowledge will come by the combined efforts of biologist and physicist. One of the happiest omens for this development, be it in the clinic or in the laboratory, is the mutually helpful attitude, recently expressed in several notable actions, of the four supporting bodies to which reference has been made.

PARLIAMENTARY REPRESENTATION OF THE UNIVERSITIES.

EVERY alteration in our national suffrage, as it has been made, has been designed or presumed to mark constitutional progress, in that the extension or limitation of the right to vote will dissipate an undue influence of wealthy or privileged persons. A measure to be introduced at the reassembling of Parliament would abolish the representation of the Universities, and will make its appeal to those who are particularly anxious to free parliamentary representation from the reproaches of class distinction and plural voting. It may be well to point out that the maintenance of the parliamentary representation of the Universities need imply no such abuses, while there are sound popular reasons for leaving the position of the Universities as it now stands. At any rate, an inquiry into the facts by a committee appointed to oppose this measure has resulted in a memorandum in which the situation is described as being quite different from that which it is generally believed to be. At the General Election in 1929 seven University constituencies returned 12 members with about 200,000 voters, but owing to extensions of franchise, created by the University constituencies themselves, these numbers will automatically and quickly increase, while the increase will be due mainly to the recruiting by the Universities of students from the secondary schools. In other words, so far as any plural voting is made possible by the University representation, it will not be a privilege enjoyed by the wealthier classes, but a recognition of an additional vote to men and women who have successfully passed through a course of higher education. But the word "additional" must be qualified by the fact that the University constituencies by reason of their make-up provide for the franchise of a large number of men and women who would otherwise be without a vote at all: it is not a question of plural voting in many cases, but rather of removing disenfranchisement. For the University voter can vote by post or by proxy, when he or she cannot by reason of avocation register a personal vote. Probably the vote for the University is the only one which many doctors are able to record.

THE MERSEYSIDE VOLUNTARY HOSPITALS.—The total expenditure of the Merseyside Voluntary Hospitals in 1929 was £322,001 and in addition £3288 for convalescent treatment and after-care. The total income from all sources (excluding legacies) was £268,753. The number of in-patients treated was 55,160 and of out-patients 203,148. The number of patients sent to convalescent homes was 1228. The penny-in-the-pound fund has 250,000 enrolled contributors, but the contributions fall short by £40,000 of the sum required for the maintenance of the contributors to it and their dependants, who together number about 750,000 persons. It costs about £50,000 a year to maintain them in the hospitals. Part of the sum thus required is obtained from the Hospital Sunday collections.

ANNOTATIONS

DIET IN DIABETES.

THE question of the most suitable diet in diabetes mellitus is a very difficult one. Since Allen's work in 1914 the proper amount of protein has been almost settled at about 1 g. per kg. of body-weight; (0·5 g. per lb.); but amounts of carbohydrate and fat vary widely. Before the discovery of insulin the carbohydrate was kept as low as possible, and some patients existed on 10 to 20 g. per day. The fat, on the other hand, varied from 100 to 200 g. or more. Even when insulin made it possible to increase the carbohydrate to 40 or 50 g. the fat intake was still kept very high by certain workers. During the last seven years the tendency has been to increase the carbohydrate to 60 or 80 or 100 g. in the day, and lately a plea has been put forward for complete reversal of the proportions of carbohydrate and fat.[1] Where a diet of 50 C., 70 P., and 250 F. (2817 calories) was sometimes given, the new diet would consist of 250 C., 70 P., 50 F., (1777 calories). At first sight it seems probable that so large an amount of carbohydrate will necessitate a great increase in the insulin dosage. Thus an increase of 200 g. of carbohydrate might be expected to call for 100 units of insulin. But McLeod and his co-workers showed in 1924 that the rule that 1 unit of insulin looks after 2 g. of carbohydrate is only correct when small quantities of carbohydrate are being given, and for large amounts of carbohydrate 1 unit may suffice for 4 g. Experience indicates that the extra insulin required to keep the blood-sugar normal on these large carbohydrate diets is often less than 1 unit for 4 g. and can subsequently be reduced still further. Although the diet at first sight seems large, its caloric value is really on the low side, and the principle of under-nutrition put forward by Allen is maintained. The clinical condition of patients so treated is described as very satisfactory, but one of the difficulties of deciding about the correct diet is that, since the introduction of insulin, patients look and feel well, no matter what they are eating. An observation on which Rabinowitsch lays emphasis is the decrease in the blood cholesterol. This may be as high as 1000 mg. on a high fat diet, but on a low fat diet is usually within normal limits, and may fall to 100 mg. One great advantage of the increase of carbohydrate is that the various substitutes for bread—whether the cheap variety of bran and gelatin or the expensive diabetic foods—are unnecessary and are no longer desired by the patients. On the other hand, a diet which contains so very little fat is somewhat unpalatable. In order to reduce the fat to 50 g. in the day the patient is required to abstain from all bacon, ham, or other fatty meats and cream, and to eat only 1 oz. of butter daily. These articles of food have been esteemed by diabetics and the deprivation therefore seems severe. Although the evidence in favour of the high carbohydrate and low fat diet shows that the patients keep well and require much less insulin, no evidence has been provided that they do better than on a diet which contains rather more fat and rather less carbohydrate. It may well be that the best diet is somewhere between the two extremes, but some years must elapse before this can be proved. Meanwhile the present changes constitute an advance, for the patient with diabetes need no longer make himself conspicuous by avoiding foods which contain carbohydrate.

NEW WORK ON FILARIASIS.

ABOUT three years ago Colonel S. L. Brug found in the blood of man in the Dutch East Indies a sheathed nocturnal microfilaria which when stained with hæmatoxylin differed from *Mf. bancrofti* in the shape and nucleation of the tail and in the clarity of the anal pore; moreover, *Culex fatigans* resisted infection by it. He regarded it as a new species, and named it *Mf. malayi*. At a meeting of the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine on Jan. 6th Dr. Brug explained the present position in a valuable paper which was followed by an informative discussion. The intermediate or larval host of *Mf. malayi* has hitherto escaped detection; but Dr. Brug now reported that ready development occurred in two species of tænio-rhynchus. Of *T.* (*Mansonioides*) *annulipes* used by him 93 per cent. became experimentally infected, and of *T.* (*M.*) *annulatus* 83 per cent.; in wild specimens caught in houses the similar percentages were 1·2 and 1·9. Development proceeds on lines very similar to those of *F. bancrofti* except that a caudal bunch of nuclei is formed, and a curious nail-shaped structure at the anus. Infection seems to cause a heavy mosquito mortality, an observation paralleled by that of P. H. Manson-Bahr on the non-periodical microfilaria of Fiji. It may be noted that the breeding-places of these mansonioides have hitherto eluded detection.

On the clinical side Dr. Brug found that infectio with *Mf. malayi* was apt to be accompanied b elephantiases of the legs, and that with *Mf. bancrof* by hydrocele; moreover, contrary to the ordinar experience with infection by the latter, in whic infection microfilariæ are apt to disappear whe elephantiasis comes on, *Mf. malayi* was frequentl present in elephantiasis cases. This associatio between elephantiasis and *Mf. malayi* induce reference to the observation of V. T. Korke[1] tha atypical forms of *Mf. bancrofti*—forms which Kork likened to *Mf. malayi*—were associated with elephan tiasis, and the typical ones with hydrocele; a remar which drew from Dr. Brug the opinion that Kork had seen *Mf. malayi*, thus implying a belief tha the newly separated form was widespread. In n case had Dr. Brug been able to obtain a post-morte examination, so that no adult forms had bee examined; their characters are accordingly unknow In view of the commonness of filariasis it is surprisin how few adult worms have ever been found an examined; these new observations are likely to alte this unfortunate position, and the search will n doubt take into consideration the findings o O'Connor and his colleagues[2] that the adult worm do not necessarily or perhaps mainly lie in the larg lymphatics but are scattered or aligned in the limbs As to the separation of elephantiasis and hydrocel on the ground that they are apt to be caused b different species of filaria, it is well to recall tha H. W. Acton and S. Sundar Rao,[3] whose observation included Orissa, explained the different incidence these manifestations which they found in different parts of India as being due to difference in the amount of infection which was being acquired. They inferred that in hyperendemic regions the first glands reached were severely damaged, resulting in elephantiasis usually of the leg, while in regions of low endemicity the main damage was in the juxta-aortic series with consequent hydrocele, chylocele, and lymph varix of the cord. These writers mentioned no difference in the morphology of the microfilariæ as being associated with the differing lesions. Moreover, Dr. Brug reported that, in villages where both kinds of microfilariæ were found, mixed infections occurred oftener than the laws of probability would suggest, which seems to imply that all factors are not yet known. It is only by their discovery that divergent views will be reconciled.

For many years nocturnal filariasis has been considered as a field with little scope for further morphological discovery. These helminthological observations by one who has made his mark in work on spirochætes, protozoa, and insects, and who modestly refused at the meeting to be considered as an expert on helminthology, shows what plentiful scope there still is for that individuality and wide view characteristic of Patrick Manson. Team-work is spectacular in the volume of its output, but here is yet another instance that it is no necessary prerequisite for the output of valuable, stimulating, and original work.

INTRAVENOUS ANTISEPTICS FOR UTERINE INFECTION.

THE treatment of puerperal sepsis and uterine infections is generally considered to be purely local so far as antiseptics are concerned. At a recent discussion in Dublin Dr. R. J. Rowlette definitely said[1] that in no condition of bacterial infection was there any reason to suppose that antiseptics introduced into the blood stream had any value, and that the only useful systemic method was vaccine or serum. This statement may be considered unduly pessimistic in the light of recent work of Dr. Joseph L. Meyer[2] at the Northwestern University Medical School. He records the results of a number of experiments on dogs. The abdomen was opened and both uterine horns were ligated with double silk ligatures near the body and at the fimbriated end, to prevent discharge of pus into the vagina or the abdominal cavity. A bacterial culture (1 c.cm.) of staphylococci, streptococci, or colon bacilli obtained from patients was introduced by a syringe into the left horn just below the fimbrial ligature. The needle was passed diagonally through the musculature and then parallel with the mucosa before entering the lumen. This made a valve-like opening which prevented leakage in most places. Acriflavine, 1 c.cm. of a 1 per cent. aqueous solution per 10 pounds of body-weight, was injected either immediately or 24 hours or 48 hours after the operation. This dose is about one-half to one-quarter of the amount generally used in therapeutics.

The results were quite striking when the dye was injected immediately after inoculation, but of course the experiments were not applicable to human pathology, as the practitioner is not aware of infection until symptoms appear. Temperature records showed that symptoms were present 24 hours after inoculation, and even when the treatment was instituted at this time it had a distinctly beneficial effect. The average temperature of the treated animals was definitely lower and dropped by lysis. When acriflavine was injected 48 hours after inoculation there was also a beneficial effect, though a less marked one. These experiments are comparable with the conditions of practice, except that the number of organisms introduced was probably greater than would occur in an ordinary puerperal infection. After 24 hours there is a rise in temperature and the mucous membrane of the uterus is deep red and swollen. The control animals showed a remarkable difference in pathological conditions from the treated animals; the uteri of the former were more than twice the size of those of the treated group, and intensely swollen and engorged. In some cases sterile cultures were obtained from an infected horn after acriflavine treatment. According to Dr. Meyer's results intravenous acriflavine in appropriate doses would be worth trial in early cases of uterine infection.

MALARIAL TREATMENT OF GENERAL PARALYSIS.

FEW therapeutic innovations have been so hotly discussed as the non-specific treatment of general paralysis, and a recent survey by Prof. Wagner-Jauregg, the pioneer of this method and the exponent of malarial treatment in particular, is therefore of special interest.[1] The danger of malarial treatment, he says, is a thing of the past. The intracutaneous injection of malarial blood reduces the incidence of the severe quotidian type of fever, and the likelihood of inducing the desired tertian type is still further increased if the blood belongs to an incompatible group. The attacks can be stopped with quinine or plasmoquine—though this latter drug establishes tolerance in the parasite—and the course can, if the patient seems to lack stamina, be given in two parts, separated by specific treatment and re-education. The range of contra-indications has therefore been greatly reduced and age is no longer a bar to treatment. The efficacy of the method can, of course, only be judged by the increase it produces in the number of remissions. Rear-Admiral Meagher's figures, taken from English mental hospitals,[2] which Prof. Wagner-Jauregg quoted, are certainly impressive but, as the Viennese worker points out in another connexion, it is not scientifically accurate to match results from one group of hospitals against results from another. Nevertheless, as evidence of the permanence of the remissions, he adduces three patients who were discharged after treatment in 1917, of whom two are still well and the other has died, free from paralysis, in 1928 of an intercurrent complaint. Moreover, Dr. Dattner's results from the Vienna Psychiatric Clinic, which Prof. Wagner-Jauregg describes as unique in their scope and accuracy, show that out of a total of 129 patients treated between 1922 and the beginning of 1924, 53 are still enjoying full remission and capable of following their occupations. But for unconnected intercurrent disease the number would, he says, be 57. According to Dr. Dattner, the reaction of the cerebrospinal fluid becomes negative or weak positive in many of even the unbenefited cases. Prof. Wagner-Jauregg quotes the observations of Sträussler and Koskinas that the brains of paralytics who had died during treatment showed an unusual increase in the inflammatory and proliferative processes, and states that those who die some time after the treatment show considerable retrogression of the inflammatory symptoms. Unfortunately, the number of patients in full remission coming to necropsy through intercurrent disease is very small, but the finding of Sträussler in one case is certainly interesting: that paralysis could not have been diagnosed on anatomical grounds without knowledge of the history. Prof. Wagner-Jauregg is, however, perhaps a little optimistic in his belief in the possibility that injected malaria may produce a pathological cure. He points out that the behaviour of the spirochætes in treated patients has not yet been pathologically investigated, but that, according to the best authorities, they probably vanish from the nervous system of patients in full and long-standing remission.

[2] See THE LANCET, 1929, ii., 402, 671.

Prof. Wagner-Jauregg reviews the other methods of non-specific treatment. Having tried and discarded most of the non-bacterial methods many decades ago, he has little to say of them except to speak generously of sulfosin, the rival which Dr. Knud Schroeder has prophesied will take the place of infection-therapy. Rat-bite fever, he thinks, may become a useful alternative to malaria in certain patients. Meanwhile, he considers, malaria holds the field, and as a prophylactic in patients with a persistently positive cerebro-spinal fluid is unmatched. In dealing generally with other methods, he points out the obvious fallacy which handicaps the discussion of nearly all of them: the smallness of the groups treated, the absence of controls, and the assessment of results far too soon after treatment. He states, quite justly, that it is not fair to compare the results in different institutions and that, in the presence of a remedy which has proved itself to be at least of some potential value, the experimenter is not justified in leaving a number of cases untreated to serve as controls of the progress of a group treated by a new method. He makes a strong plea for what he has termed "simultaneous research": the treatment of a large number of alternate cases by two methods in the same institution, and the observation of the results over a period of some years.

RADIOGRAPHY OF THE LIVER AND SPLEEN.

THE astonishing success of cholecystography prepared the way for the new method of "excretion urography" by which opaque substances are injected intravenously and photographed with X rays when they reach the urinary tract. It appears that means have now been devised for defining the outline of the liver and spleen in similar fashion. Hitherto radiologists have used artificial pneumo-peritoneum for exact definition of these organs, but the procedure described by Dr. P. Radt at a recent meeting of the Berlin Medical Society has advantages beyond its greater simplicity. It is based upon the fact that the reticulo-endothelial system, comprising especially the reticular and endothelial cells of the spleen and the Küpffer cells of the liver, have the property of taking up certain foreign colloids in a selective manner. These substances, therefore, tend to accumulate in the liver and spleen, and a search was made for one which was opaque to X rays. Radt employed first, tordiol, which is a thorium-dioxide "sol," and later a preparation in which it is combined with carbohydrate. This compound is stable and is not precipitated by the body fluids. After numerous animal experiments he injected it intravenously into 20 patients and reports that there were no serious ill-effects though occasionally there was slight malaise, with fever and shivering for a few hours. Animals injected as long as one and three-quarter years ago have remained in perfect health, and in the patients examined no changes have been found in the blood or urine except a slight temporary mononuclear leucocytosis and transitory fall in hæmoglobin. The films reproduced by Radt in his paper[1] show clear shadows of the liver and spleen. In cases where the normal structure of these organs is grossly altered the colloid has not been taken up and the shadows are indefinite. This happened, for example, in cirrhosis of the liver where the excessive fibrous tissue failed to take up the thorium. Again, where there are secondary deposits in the liver, clear areas are seen in the position of the metastases, and films illustrating this are characteristic. The spleen shadows seem to be of assistance in outlining size and shape rather than structure. The preliminary accounts of this new "hepato-lienography" suggest advancing possibilities in radiological diagnosis, but until we know more about the most suitable colloid there is evidently need for caution.

REGULATION OF BLOOD DONORS IN NEW YORK.

SINCE Landsteiner published his work on isoagglutins in blood the practice of direct blood transfusion has widely increased, and in New York it led to the establishment of a number of commercial agencies whose purpose was to provide persons prepared to act as blood donors. This development did not escape the watchful eyes of the city health department, which under Dr. Shirley W. Wynne maintains the high reputation inherited from the administration of the late Dr. Hermann Biggs. Inquiries were made which showed that some of the agencies exercised little control in the selection of the donors, being chiefly interested in profit-making; donors unsuitable for particular cases were provided, and it is stated by the Health Department that several were found to be infected with syphilis. The Department conferred with representatives of the medical profession, hospitals, and reputable blood donor agencies, with the result that the City Board of Health on Nov. 21st of last year added to the city's sanitary code a set of regulations which will enable the New York health authority to exercise suitable control. For the purpose of the regulations a blood donor is defined as a "person who holds himself out as willing to dispose of his blood, or who offers his blood, or whose blood is used for transfusion purposes for a fee;" while the definition of a "blood donor agency" is "any office, registry, place or establishment which employs, engages or supplies or advertises or holds out to employ, engage or supply any person or persons whose blood is or may be used for transfusion purposes." Under the regulations it is illegal to act as a blood donor without a certificate of registration issued by the Department of Health, or otherwise than in accordance with the regulations. It is also made illegal to "conduct, maintain or operate" a blood donor agency without a permit from the Board of Health, and the agency must conform with the terms of the permit and with the regulations. The action taken by the New York Board of Health affords another instance of the wide legislative powers in relation to public health with which American cities have been entrusted. In this country it would be necessary to pass an Act of Parliament to secure the control over the practice of commercial blood donors which in New York has been effected by means of regulations made by the City Board. And it is noteworthy that the Board did not make this extension of the law until the question had been fully explored in conference with the medical profession.

A COMMITTEE ON NUTRITION.

THE Minister of Health has appointed a committee to advise him on the practical application of modern advances in the knowledge of nutrition. The members are: Prof. Major Greenwood, F.R.C.P., F.R.S. (Chairman); Prof. E. P. Cathcart, M.D., F.R.S.; Sir Gowland Hopkins, F.R.C.P., P.R.S.; Miss Jessie Lindsay; Prof. E. Mellanby, F.R.C.P., F.R.S.; and Prof. V. H. Mottram. They will hold office until Dec. 31st, 1933, and will then be eligible for reappointment. The Secretary of the Committee will be Mr. F. R. Hudson of the Ministry of Health.

WORK OF THE ROSS INSTITUTE.

THE industrial antimalarial committee of the Ross Institute has lately reported on interesting work which it has done in different parts of the world. At the Institute's Assam branch Dr. G. C. Ramsay, after dissection of about 50,000 anopheles, believed to be a world's record, found that practically only *A. minimus* was infected. It requires for breeding, clear, slowly running water exposed to sunshine. By applying to such water oil or Paris green, or by growing suitable shade-producing plants there, sickness was reduced, the drug bill halved, and the efficiency of the labour force doubled. A note of the actual balance-sheet concerned would make a valuable addition to the report; at all events the change took place after "bonification" had proved a great disappointment. Malaria, and not hookworm infection, is the primary cause of anæmia here. Ramsay's statement that there is no relationship between hookworm infection and the amount of sickness in his gardens is not likely to prove correct. When the power loom replaced the hand loom the effect was too striking for it to be realised that later the question of four or eight looms to a weaver would be a crucial economic one; but the economic truth was always there. When the main source of local anæmia, the plasmodium, is under control, the hookworm will doubtless show itself as an economic handicap as heavy in Assam as in those other parts of the world where apt tests have been made.

The Institute has been active in South Africa. Since its expedition to Northern Rhodesia the malarial incidence is said to have fallen in one mine from 27 per cent. per month to eight cases per month in a total population of between 8000 and 10,000. Sir Malcolm Watson found that some swamps in Natal and Zululand were free from malaria and some not, a puzzling problem which will not be solved till the local anopheline host has been determined. In conjunction with the Shell Trading and Transport Company work is being carried out in Burma to determine the best larvicidal oil mixture for use in hot or in cold weather, for places where the water vegetation should be killed, and for those where it should be destroyed. Sir Malcolm, after drawing attention to the warning note which we sounded soon after the introduction of plasmoquine,[1] states emphatically that this drug is no substitute for quinine, and holds that much more detailed work is needed before it can, for example, be concluded that it does in fact kill gametocytes, seeing how widely these vary in numbers from day to day in peripheral blood. Another striking tribute to the Institute refers to the effects of control measures advised by Sir Malcolm at the Noamundi Mine of the Tata Iron and Steel Company. In the Noamundi mine blackwater fever has disappeared and all primary malaria cases are believed to have been eliminated. Colonel R. Knowles, I.M.S., questions whether even in Panama anything like it has ever been seen. But it seems a somewhat ungrateful return for such unstinted praise to refer in the report of the meeting to the venerable and distinguished publication of which he is joint editor as the *Indian Medical Journal.*

These are some of the Institute's useful activities. There can be no better indication of its appreciation of the world's needs than the remark of the chairman of the committee that research and practical work on the malaria problem are almost in their infancy.

MILK AND THE GROWTH OF CHILDREN.

THE value of regular additions of milk to the ordinary diets of school-children has been demonstrated once again in a test carried out with 20,000 children attending schools in Lanarkshire.[1] The arrangements were in the hands of the Department of Health for Scotland and the education authority of the county of Lanark and were assisted financially by grants from the Empire Marketing Board and the central advisory committee of the Distress in Mining Areas (Scotland) Fund.[2] The heights and weights of all the children were measured by a special staff of doctors and nurses at the beginning of the feeding period and again at the conclusion of the experiment some four months later. The whole of the milk used belonged to category Grade A (tuberculin tested), one-half of it being given raw and the other half pasteurised. In each school one-half of the children acted as controls, the other half receiving ¾ pint of either raw or pasteurised milk. The results of the test support the conclusions reached by other workers —namely, that additional milk definitely accelerates the rate of growth as measured by increase both in height and in weight. The differences between the milk groups and the control groups were small, as would be expected in a test lasting only four months. In most of the age-groups the average increase in weight was 4 to 6 oz. more in the children receiving milk than in the controls, and the average increase in height was about one-tenth of an inch more in the milk groups. Boys and girls exhibited on the whole the same degree of improvement and the older children (7–11) showed quite as much improvement as the younger ones (5–6). No significant difference was observed between the growth-promoting effect of raw and pasteurised milk. No statistical evidence of any effect of the milk other than that on growth was recorded, but the school teachers formed the impression that the physical energy and animal spirits of the milk-fed children were stimulated so that they became more boisterous and difficult to control. Some of the teachers expressed the opinion that an increase in mental alertness was noticeable as the result of giving milk, especially among the younger children. The results of the test support the policy of the Education (Scotland) Act of 1930, under which local authorities are empowered to supply graded milk to school-children. It is expected that this power will be widely used in the near future and will result in a noticeable improvement in the physique of the Scottish race. Incidentally it is hoped that the great increase in the consumption of graded milk which would result from the general adoption of the scheme of giving a regular supply to school-children will encourage the production of milk free from tubercle bacilli throughout the country.

THE THERAPEUTIC USES OF IRON.

THE pursuit of new drugs should not lead to the neglect of old ones, as Dr. Philip Hamill, who took the chair at the Section of Therapeutics of the Royal Society of Medicine on Jan. 13th, pointed out when opening a discussion on the therapeutic uses of iron. Dr. L. J. Witts, who had been investigating the effects of iron on chlorosis in young persons, and on chronic microcytic anæmia in those of middle life, was able to place his conclusions before the meeting. Chlorosis, he finds, responds readily to treatment with iron and ammonium citrate, the patients sometimes showing an increase in hæmoglobin from about 38 to 85 per cent. over a period of 6 or 7 weeks; relapse is rare. The microcytic anæmias of middle life are usually associated with absence or diminution of hydrochloric acid secretion, glossitis, splenomegaly, and, in some cases, dysphagia. He found that 17 patients with anæmia of this type recovered on doses of grs. 60 to 120 of iron and ammonium citrate given daily over a period of 4 or 5 months. Those treated with doses of less than grs. 60 showed no definite improvement, and he does not recommend reduction until the hæmoglobin has risen to a normal level; as there is a tendency towards relapse in these cases the patient should persist with a maintenance dose of not less than one-third of the curative. A lag of about a month is to be expected before the treatment begins to show any result. Another aspect of the chronic microcytic anæmias was discussed by Dr. D. T. Davies; he mentioned the high viscosity of the gastric juice and the reduction in pepsin which accompanies the hypochlorhydria or achlorhydria. After giving histamine to patients with microcytic anæmia he had found an increase in pepsin and a fall in the gastric pH consequent on the appearance of more hydrochloric acid. He thought that some form of gastritis might underlie the condition, which was possibly an alimentary rather than a blood disorder. The meeting agreed with Dr. Witts in his view that liver or stomach extracts failed to provoke a reticulocyte crisis in anæmias of the chlorotic and microcytic types, and this led to the consideration of the value of iron in pernicious anæmia. Dr. Janet Vaughan had observed cases in which Addisonian anæmia was associated with a mild iron deficiency; in a certain number of these the addition of iron preparations to liver treatment led to an improvement in the blood count. Dr. Izod Bennett was able to confirm this. He referred to the origin of liver therapy; liver had been employed, in the first place, because it was rich in iron; now the iron-free liver extract was given and was found to be equally effective. He thought it conceivable that it was not the iron and ammonium citrate which produced recovery in chlorosis but some impurity in the preparation, such as copper; Dr. Witts, however, thought the proportion of copper present insufficient to have a therapeutic action. The value of the ferrous salts was emphasised by Dr. Witts and Prof. J. A. Gunn; they were effective in much smaller quantities than the double salts, gr. 4 being a suitable dose for an adult, and they usually produced good results within six weeks of the beginning of treatment.

Dr. Helen Mackay said she had given iron preparations to infants during the first year of life and had found that it was well tolerated if the initial dosage was small. Given to a series of artificially-fed infants, iron had occasioned a remarkable rise in hæmoglobin as compared with control cases. Anæmia was found to be common in breast-fed as well as artificially-fed infants, showing that no one particular method of feeding was at fault. Infants small at birth grew relatively more quickly than others and showed a greater tendency to anæmia. Dr. Mackay drew attention to the spontaneous and temporary rise of hæmoglobin which occurred in all infants between 2 and 7 months of age, and which made caution necessary in estimating the results of the iron treatment during that period. In addition to the improved hæmoglobin content, Dr. Mackay was able to demonstrate two other effects of iron when given to infants. The first was a reduction in illness amounting to a diminution by one-half of the attack-rate in the children receiving iron as compared with those untreated. The second was a marked increase in the rate of growth of those treated. Dr. Bradford Hill, as a statistician, confirmed her figures; those dealing with the attack-rate he had investigated with great care, but could not find a source of error.

STAFFING MUNICIPAL MATERNITY HOMES.

THE question whether practitioners are to be allowed to deliver patients confined in municipal maternity homes has arisen in an acute form in Birmingham. Until recently the family doctor who had given antenatal supervision was summoned when labour set in, but in the view of the local Maternity and Child Welfare Committee the variation of standards and methods of treatment adopted by private practitioners involves an element of risk, and it is now proposed to appoint full-time medical officers as accoucheurs. Obviously it is easier to ensure smooth and efficient work if all labours in one home are conducted under one direction and responsibility, but convenience alone should not, we feel, be the main consideration. If the science and practice of obstetrics is to make progress, continuity of observation and service from early pregnancy until the puerperium is essential. In the past, when far more reliance was placed on pelvic measurements as a factor in prognosis, careful records of antenatal examinations were valued as impersonal documents. Nowadays the dimensions of the pelvis alone are known to be a poor guide to the prospects of an easy labour and the estimation of relative size of fœtal head and pelvic outlet is recognised to be difficult; nor, in cases where toxæmia is suspected, do the results of periodical tests of urine reveal clearly the outlook unless they are correlated with other circumstances by a trained observer. Only experience in following up cases can teach judgment; little can be learnt on the one hand from antenatal observation which is cut short at the crucial moment, or on the other from skilful management of abnormal conditions whose genesis is obscure. It is therefore greatly to be hoped that in Birmingham as elsewhere a way will be found to prevent practitioners who have recommended their patients to seek admission to maternity homes for confinement from being penalised by having to relinquish their responsibility.

A POST-GRADUATE COURSE

MOTIVES AND MECHANISMS OF THE MIND.*

III.—HOW THE MIND WORKS.

THE DEVELOPMENT OF MIND.

It is easier to understand the symptomatology of mental disorders if we have a clear picture as to how the mind has developed and of what parts it is composed. The ordinary conception of "mind" is that it is solely concerned with processes of conscious thought, but a little consideration will show that this is not true. A great deal of the difficulty which we experience in understanding ourselves and our patients is due to this erroneous conception that mind is only occupied with conscious thinking processes. It is for this reason that the term "unconscious mind" has proved such a difficult one to understand. If "mind" was "consciousness" how could there be such a thing as an unconscious consciousness? But is mind only consciousness, and if it is more than that, what is it?

Let us begin with the broadest view of the initial development of the nervous system. With the progress of differentiation of function, it became increasingly necessary for the organism to evolve a central selective station which might inhibit certain impulses whilst promoting others. In the ordered interaction of the nervous system, the different parts of the human organism are enabled to perform their work as units coöperating in a team. For example, the lungs and the organs of digestion, by co-relation and inhibition in the nervous system, perform in health their functions harmoniously and "unconsciously." Consciousness of the existence of a certain organ is usually a sign that that organ is in a state of disorder.

On a level above that of the coördinative and inhibitive cell stations we have the field of emotion. We may describe an emotion as a feeling associated with a wish or need. Primarily, emotions are associated with instincts, and although psychologists are not agreed as to what exactly the fundamental instincts may be, they are agreed on the general principle that instincts and emotions are, as it were, two points of view of an internal tendency to behave in a certain way in response to a certain stimulus. For instance, with the development of a need for nourishment on the part of the tissues a feeling of hunger is felt, and the behaviour of the organism then tends to be directed in such a way as to satisfy the need for food. The need is felt and, other needs being in agreement, the hunger feeling can be satisfied. On a higher level than that of the nutritional may be cited, as an example, needs associated with a feeling of fear and the organism's resultant behaviour. The feeling of fear is associated with a need for the preservation of the organism from the threat of the apprehended danger. Behaviour may be directed either towards escape or towards overcoming the threat. Other impulses, such as nutritional, then undergo inhibition and the activity of the organism is centred upon its reaction towards danger.

Another example of an instinctive feeling is that associated with sex. The urge of propagation, with its elementary biological function of preservation of the species, is liable to overcome in its intensity all other impulses, except those of self-preservation.

In animals and simpler organisms, what we understand as consciousness is either non-existent or only present to a very minor degree. Much of their behaviour is conditioned by simple reflexes or habit into which consciousness does not enter. Self-consciousness, the awareness of the self as an integral individual distinct from other individuals, is one of the earliest forms of consciousness and one of the least highly developed. Awareness of alternative courses of conduct, with its inevitable conflict with other impulses, only arises in a late stage of human development, and it is the beginning of a further extension of the field of consciousness. Ultimately it is enlarged to include not only the awareness of concrete external objects and internal impulses, but also a discrimination of abstract ideas of which the variety is almost without limit. Such development takes place through associative paths, in which a series of links is developed as a comparison with and extension from past experience. All later experience is, therefore, more or less intimately associated with something that has previously happened. Whilst it is entirely new, experience has no meaning for us at all, and it is only through its association with past experience, with something old, that it has *meaning* or *value.*

A simple way of understanding the problem of mental development is to relate it to the rings which develop, year by year, in the cross section of a growing tree. The central ring is the oldest part of the tree and successive rings represent the "experience" of the tree year by year. In the accompanying diagram (Fig. 1) there are five rings which may be taken as representing the development of the human mind, but not in periods of years. Each ring represents a successive stage of development by experience. The central, most elementary and oldest ring is that of the *coördinative reflex cell stations* in the brain—e.g., those which control the action of the physical organs of the heart, lungs, &c. The second ring is that associated with the *instinctive-emotional* life. It is the centre associated with energy and movement, the wishes and needs of the organism in its relation to life and experience. The third ring represents the development of *qualitative* feelings. Life and experience at this stage have definite feeling values, feelings of pain and pleasure, good and bad, but the level of such feelings can hardly at present be called "conscious." It is in the next stage that a further

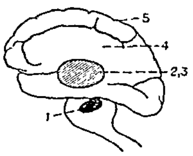
FIG. 2.



The brain. (Semi-diagrammatic.)

1. Coördinative cell stations.
2. Dynamic level—instinctive.
3. Emotional level—feeling states.
4. Pictorial level.
5. Abstract rational level.

---

* A course of 12 lectures delivered under the auspices of the Tavistock Clinic, Tavistock-square, by Dr. E. Graham Howe during the autumn session of 1930. The first and second lectures of the series appeared on Jan. 3rd and 10th, 1931, respectively.

differentiation of feeling values takes place at what is called the level of "*picture-thinking.*"

At this stage awareness of an external world sees experience and external stimuli in terms of crude concrete objectiveness. Discrimination has picked out certain outstanding objects and endowed them with their own feeling tone. Consciousness is, at this level, becoming differentiated, but it is concrete, pictorial, symbolical, and always associated with a strong feeling tone.

The last level is arrived at with the outermost ring, which is called *rational*. At this point awareness of an external world has become differentiated into a realisation of the finer distinctions and comparisons. The feeling tone is less and symbols have become split up and qualified so as to be abstract vehicles rather than concrete pictures, and this represents the level of intellectual consciousness.

Fig. 2 shows this principle applied to the various levels of the human brain.

(1) Indicates the central coördinative cell stations concerned with organic function (medullary ganglia).

(2, 3) The basal ganglia which are probably associated with the fundamental "energy" of life and with emotional states. It is interesting, and it should make us tentative in all our conclusions, that we are still entirely unaware as to what the source of the dynamic of life may be, or as to the manner of its operation. But general indications are in favour of the basal ganglia having something to do with it and, as long as it is only held as a working hypothesis to be abandoned as soon as anything better or more certain takes its place, there is no harm in the tentative acceptance of this as being true.

(4) The deeper layers of the cortex indicated by (4), with all their associated paths to the basal ganglia and different parts of the cortex, possess a larger and a cruder type of cell than the superficial layers of the cortex and may perhaps be assumed to function in the way described as "picture-thinking."

(5) This is the superficial layer of the cortex in which the higher, more abstract, processes of reason take place, but each successive higher level can only be understood as being derived by a process of differentiation and modification from earlier and more primitive methods.

The Function of Thinking.

Those who are accustomed to think of the function of the mind as being entirely conscious naturally make the mistake, since they are aware of the dynamic quality of life, of thinking that consciousness is the centre of dynamic activity. It is not. The function of consciousness is selective and it probably possesses no energy of its own. *The energy of life is to be found in the deepest levels which are prior to and primarily independent of consciousness.* This is the level of instinctive wishes or needs, and it is not *necessary* for these to enter consciousness. Many are dealt with by an automatic process without entering consciousness at all. Some, which originate in a distant racial past, do not enter consciousness because they are not related to any individual consciousness of "now." Others enter consciousness as *wishes* and the function of consciousness is to determine how the wish may be gratified in the most satisfactory way without causing trouble. The function of consciousness, then, is selective and adaptive, but it is not dynamic. *It is a means to an end and not an end in itself.* The end, from one point of view, is the gratification of the instinctive wishes and needs which activate human behaviour. From another point of view, consciousness may be said to provide a channel for the fullness and freedom of emotional self-expression. In any case its selective function is to fulfil the needs of life without conflict or discord. The "will" may be defined as that part of the individual's instinctive energy which enters consciousness and is directed towards unity, freedom, self-gratification, and self-expression.

THE SAVAGE, THE CHILD, THE NEUROTIC, AND THE GENIUS.

It is to be expected that the minds of the child and the savage would show something in common, since the savage is phylogenetically infantile and the child is ontogenetically primitive. The fifth layer i both, that of abstract reason and higher synthesis, is as yet not fully developed. In consequence, the layers associated with uncoördinated wish fulfilment with a strong emotional content and a tendency towards pictorialising, are those which we would expect t find most in evidence. Both in the primitive min and in the mind of the child the activities are mainly those of wishing, feeling, and picturing, withou strong rational or coördinative development.

It is now necessary to define what we mean b "imagination," because of its association with pictur thinking. Imagination may be defined as an ability t pictorialise life without relation to experience. If wis fulfilment is associated with a strong sense of fear the dangers of reality, imagination may becom phantasy. Phantasy is a flight from life, wish fulf ment being directed inwards as an escape fro experience of reality, owing to the association reality with the feeling of fear.

It was stated in Lecture II. that an exaggerat tendency towards fear feeling was characteristic of t nervous temperament. All those who are thus ove sensitive to fear stimuli are uncertain in their behavio reactions. Where fear is strong, the tendency towards false adaptation and neurosis. The neurot may also be compared with the child and the primiti savage, because of the same strong tendency towar picture-thinking which exists in all three.

Besides being a prominent characteristic in t savage, the child, and the neurotic, the faculty imagination is also predominant in those who a assigned the quality of "genius." It has often be observed that genius and a tendency to "neurosi go together. What is the cause of this associatio Both the genius and the neurotic are imaginati sensitive to external stimuli and emotionally responsi In both the level of picture-thinking is stron developed and both are sensitive to primitive a innate sources, of an unconscious racial characte But whereas the neurotic is inclined to dissocia imagination from life—living in terms of phantasy there is a quality of reality in the genius whic perhaps owing to an increased "energy" factor some innate quality of technical ability, obtains mastery over life and achieves self-expression throu the work of his artistic creation. The genius uses t material of reality as a check upon his imaginatio and to innate creative ability adds an acquir development of technical knowledge. The neurot has the same source of inspiration, without the sa creative ability or attachment to reality.

PICTURE-THINKING.

It may have been considered arbitrary to gi picture-thinking a place of importance as the sour from which a more abstract type of consciousne has been developed. Let us consider, therefore, so examples of what is derived from this tendency t make pictures.

The first means of communication between o individual and another was probably by gesture, whic is a method of making pictures with the hands. further development of the pictorial method o intercommunication was by the development o writing, and this further extension was made possib by the greater pictorial aptitude of some kind of stick. As mastery of materials was gained, drawing and painting were developed as a means of pictorial self-expression and intercommunication. Language, which began by gesture, was developed by means of "picture noises," and the pictorial element in language has always been a method by which meaning has been conveyed. Slang is particularly interesting from this point of view. It is essentially picture-talking, whether it is of the familiar English type such as "letting the cat out of the bag," or the modern American variety of "spilling a bibful" or "the kitten's pants." The picture-making tendency is most freely utilised in poetry, where simile or metaphor convey meanings and emotions which more abstract forms of expression are unable to convey.

> "I will go down to the great white mother,
> Mother and lover of man, the sea.
> I will go down to her, I and none other,
> Kiss her, caress her and mix her with me."
> *Swinburne.*

Other forms of primitive picture-making by means of words are the fairy tale, nursery rhyme, folk-lore, myth, allegory, and parable. The last two only differ from the others in conveying a moral.

There is one characteristic in all forms of picture-making which is very liable to be overlooked. We are inclined to look at the picture as *something in itself* and to miss the fact that its sole function has been to convey the *meaning* quite apart from itself. For instance, a political cartoon of a donkey with a human head at either end, as a picture by itself might be regarded as a zoological monstrosity. It has no meaning without *interpretation* and this applies to all cartoons. Their purpose is to convey a meaning, and before the meaning is appreciated the picture requires interpretation, which depends upon other knowledge of events previously possessed by the interpreter. In other words, it requires association with previous experience. However, much of this "picture-writing" has lost the meaning which it was originally intended to convey.

A folk tale, such as that of Cadmus (Jason) and the dragon's teeth, may be read simply as a story of a man who sowed some dragon's teeth in the ground with a very remarkable and unlikely result. But if the teeth are taken as pictures, which require interpretation before they can be understood, then in meaning they are not teeth at all, and the resultant armed men are no longer so impossible.

Fairy stories and nursery rhymes, passed down from generation to generation from a far-off past, have also lost the meaning which they were originally intended to convey. Let us take, for example, the common slang term of "fiddlesticks." A fiddlestick is a definite object of very limited usefulness which is, as a rule, not used by those who commonly use the expression "fiddlesticks." In the nursery rhyme:

> "There was an old woman who lived in a shoe,
> She had so many children she didn't know what to do"

there seems to be no association between the fact that the old woman lived in a shoe and the fact that she had so many children she did not know what to do. But perhaps another nursery rhyme may throw more light upon the problem.

> "My master's lost his fiddling-stick,
> My dame has lost her shoe."

Here we have an association between the fiddling-stick and a shoe. The fiddling-stick is a picture of something which moves up and down in a rhythmic fashion, so that if we are to interpret, with the material so far available, we find an association between something which moves up and down in rhythmic fashion, something which is like (but is not) a shoe, and the production of a great many children. That this is not an entirely unusual association will be seen from the following, taken from the notes of the patient (Case J) who had an obsessional impulse to count in fours. She wrote the following notes on her feelings as a child about her father's umbrella:—

> "When I was a child I used to have a particular attachment to my father's umbrella. I always told it where we were going and what we were going to do and expected it to be upset or pleased according to my own feelings.
>
> "It had to keep in step with my right foot. If I dropped it I was angry with it, and told it that it was stupid and clumsy and I usually shook it. When I rode on a tram or a bus I put the ferrule of the umbrella inside my shoe to keep it close to me and keep it warm. I liked best to sit on top of a bus in the back seat where I could nurse the umbrella in my arms and point out all the interesting things to it as we passed them. This was not often practicable, for, if my mother found out what I was doing she generally took the umbrella away. Sometimes I was not allowed to carry the umbrella. On these occasions I whispered to it to break or tear itself or trip up my mother. Always when I got home I placed the umbrella in the stand on my father's side and wrapped his overcoat round it, partly to hide and protect it, partly to aggravate my mother, who slapped me every time for hindering her from finding it when she wanted to go out, but I continued to do it for years."

When the patient wrote these notes she had no realisation of the meaning which the picture of the umbrella conveyed to her. To her the umbrella was an umbrella, and in the "picture" of a shoe she saw only a shoe. She did not realise that another picture of the umbrella would have been a fiddlestick and that she wished to be in the position of the old woman in the nursery rhyme.

To whatever extent language may be developed in its ultimate differentiation, it is fundamentally derived from a primitive picture form. Words are the symbols we use to express the meaning which we wish to convey and in themselves they have no value apart from this meaning. It has been well said, "words are the counters of wise men, but the money of fools."

It is not easy to appreciate that language is derived from unconscious sources, but it is a fact. The original development of words in all languages has not been the work of philologists and academicians, but they have grown by a process of unconscious selection because of the meaning which they were able to convey. The example quoted above, of "fiddlesticks," applies to far more than the development of slang. There is a most interesting field of psychological and philological research, as to the *unconscious* values and associations which have determined the use and development of certain words from their original root meanings. For example, in French there are the two similar words —"mer" meaning sea, and "mère" meaning mother. It is not by chance that two such apparently different meanings as "sea" and "mother" should be linked by similar word-forms, because the Sanskrit root of each is "ma" meaning "to create," which is usually the meaning of the sea which so often occurs in dreams.

PICTURE SYMBOLS.

Our consideration of picture-thinking has enabled us to approach the problem of symbolism with all that is necessary to understand the meaning and importance of the everyday use of symbols. A symbol conveys a *meaning* apart from itself, and, as is the case with all primitive and unconscious picture-thinking, it usually also conveys a *feeling*. For instance, the flag and the cross are symbols, simple in themselves, but pregnant with meaning and affective tone. Picture-thinking and symbolism are necessary and valuable to us for their simplicity, economy of form, and as a vehicle for the apt conveyance of emotions.

Symbolism is the material, whether we wish it or no, through which artistic and creative effort must be applied. But symbolism, apart from its undoubted value, is the source of a very subtle and serious danger. The danger is that in the riot of feeling which a symbol may arouse, its meaning may be ignored. The primitive and the child, motivated by an ever-present fear, tend to prefer the concrete to the abstract, the definite to the ill-defined, the known to the unknown. Fear of the unknown, the immaterial, and the vague is the source from which is developed much of the so-called materialistic and rationalistic philosophy. We like our words because we fear their meanings. Like a drowning man who clutches a straw, we hold on to our symbols, lest their form should escape us in those doubts which must assail us when we seek to unveil their true meaning.

To all of us symbols are a danger, but to the neurotic symbols are a disease. The life of the neurotic is full of unknown and unvalued symbolism, of forms and rituals of an obsessional character, the meaning of which has never been differentiated in consciousness. One of the functions of consciousness is to differentiate the symbol from its meaning, the means from the end, and to set free the feelings and motives which have become locked and fixed in a dead materialism of symbolism.

Dreams.

When we appreciate the meaning, importance, and danger of symbolism, and the absolute need for interpretation before the meaning of the symbol is understood, we can approach the subject of dreams.

It has already been stated that the tendency is to confuse the symbol with the meaning and to say that an apple is always an apple. It is not true. In the story of Adam and Eve, the apple was not an apple at all, but a symbol. Dreams are an activity of the "picture-thinking" layer of the mind and as such are meaningless when regarded superficially as things in themselves, but full of meaning when regarded as pictures, put in the story as symbols to convey a latent meaning which can only be discovered by interpretation.

The exact processes accompanying the physiology of sleep still remain uncertain, but as a working hypothesis it may be assumed that it is the cortical layers of the brain—i.e., those of a superficial and differentiated type of consciousness—which are in abeyance during sleep. Whether this is due to a localised cortical anæmia is uncertain, but the evidence tends to show that the depth of sleep corresponds with the depth of cortex which is inactive.

People seem to vary in the extent to which they are aware of dreaming during sleep. Some authorities state that there is always dream activity during sleep, whether the sleeper is aware of it or not. If we regard the dream activity as an activity of the deeper layer of the cortex, it would seem probable that in the deepest kind of sleep the sleeper may be below the depth of the recoverable dream layer altogether, in which case he would be in a condition of dreamless sleep. It is certain that some people are usually aware that they dream, although on waking up they may not be able to recollect its details. Others will say that they never dream, but this probably refers to the fact that they never recollect their dreams. A great majority will say that they dream occasionally, but under psychological treatment it is usually found that patients are more frequently aware of their dreams than in the ordinary course of life.

There is a common attitude towards dreams which attributes them merely to digestive disturbances. It is quite true that digestive disturbances *do* influence dreams and are usually conducive to the nightmare type. However, it is probably wrong to say that digestive disturbances *cause* a dream. A dream is the result of an impact between an internal emotional state and an external stimulus. As a rule the external stimulus has been experienced during the previous day, but from the point of view of dream-consciousness irritation of the vagus nerves may be considered as an adequate nervous stimulus sufficient to activate or modify the dream state. However, it must not be forgotten that there is still the internal emotional tension of the individual to be considered, and this is independent of all external stimuli whether due to indigestion or to the previous day's experience. A dream is an expression of the inward being of the individual—it is part of himself. It differs from consciousness in being independent of conscious inhibition, which is absent owing to the abeyance of the superficial cortical layers. It therefore provides information which may never otherwise enter consciousness as to the inward psychological state of the individual. Finally, the dream is dynami It is as much an expression of a motive as consciou behaviour is an expression of a motive. In the same way that we can inquire with regard to conscious behaviour, "What is the motive underlying this?" we can also ask the same question of dream behaviour, but without the difficulty of having to deal with superficial conscious inhibitions and distortions.

Before we proceed to a classification of dreams there are one or two further points which deserve consideration. The material which is used in a dream is described as its "manifest content," and is only to be regarded as the symbolism which conveys the meaning or "latent content." It is usually related to recent experience, and much of the content of a dream may be accounted for in this way. The question is, why the dream should have selected only such material as it does out of such a large potential source of supply derived from immediate experience? There must have been some selective process which chose this part of one experience, ignored the remainder, and linked it up with some other part of some experience which was actually quite out of context with it. This is the dramatic process of the dream which chooses just such elements of experience as it requires for its own completeness.

It sometimes happens that one item in the dream may seem to be derived from many different sources. For example, a person appearing in the dream might have the face of the patient's mother, but in other respects the person of his wife. This process, "condensation" as it is called, enables the dramatisation of the dream to take place with a maximum of economy.

There is one great difficulty in dream interpretation of which all who have tried to understand their own or the dreams of others must be aware. It has already been stated that the activity of the picture layer of the deeper cortex is expressed in picture terms, in the form of symbols which, to be understood, require to be interpreted. Perhaps in a dream I find myself by the side of a river which reminds me of a certain day on a summer holiday. Is the river to be regarded as a symbol, and therefore not as a river, or is it to be regarded as only that particular river of which I am reminded? Perhaps the dreamer is beating somebody with a stick. Is the stick to be regarded as a stick or as a symbol and therefore not as a stick? It would appear that some details of a dream require interpretation, but others are to be taken at their own face value. The difficulty is a very real one but not insuperable. All that we have to discover is the *meaning or value to the dreamer of any particular item in the dream.* This may be arrived at in different ways. For instance, of any item in a dream one may ask the patient "What do you feel about it?" "What does it mean to you?" or "What does it remind you of?" In each case one is interpreting the meaning of the picture by finding out its personal value to the patient.

Are there any universal symbols which may be taken as having a definite meaning, apart from any value which the patient may be inclined to give them? There is no doubt that it is extremely dangerous for anybody interested in interpreting dreams to assume the validity of universal symbols. It is quite true that many symbols are found in the dreams of many patients, in many different circumstances, in many parts of the world. If, however, the meaning is what the interpreter has been led to expect by his knowledge of universal symbols, then this meaning may be obtained direct from the patient as what it means to him. It is never safe to assume that a symbol in a dream means what it ought to mean. The most dangerous ground of all in which to employ universal symbolism is that associated with sexual factors. It is too easy and too dangerous to assume that a walking-stick is always a phallic symbol. It is quite possible that it has an entirely different significance to the patient; it may be no more than it seems, an additional means of support.

Are there dreams which have no meaning, no motive, and no value? It is impossible to say, but it is certain that from the point of view of the psychotherapist dreams that have a useful discoverable meaning are definitely limited in number. With infinite patience, great aptitude, and a large measure of luck, it is possible that all dreams might be found to have a meaning; but it is certain that in practice a large proportion of dreams are beyond the ability of the psychotherapist to understand with any degree of satisfaction if he is approaching his task in a critical way.

CLASSIFICATION OF DREAMS.

The following is suggested as a classification of dreams: (1) wish-fulfilment; (*a*) simple, (*b*) desired but feared; (2) anxiety (feared and not desired); (3) teleological; (4) self-critical; (5) repetitive; (6) indefinite.

WISH-FULFILMENT.

(*a*) *Simple.*—This is typical of the child's dream. He wants a bicycle and dreams that he is its proud possessor. It is a dream of simple wish-fulfilment without arousing any complex issues and depends upon the existence of a single wish without opposing conflict. The dreams of hungry explorers isolated without food on an ice-floe would be of this type. They might dream of luscious steaks, with succulent vegetables, served in spacious restaurants.

(*b*) *Desired but feared.*—What more often occurs, however, is that the wish cannot be fulfilled without a certain degree of conflict being aroused. Such are the comparatively common "death-wish" dreams. The subject matter of this dream is usually in terms of dead bodies and coffins, perhaps with added gruesome details, and the feeling tone aroused in association by the patient is that of fear or horror. A wish is being expressed in the dream for the removal of some undesirable person, but it is a wish that obviously cannot be accepted or even visualised in consciousness without disapproval. In point of fact, when one appreciates that the dream is only to be taken as symbolism, the wish is seen to be not so horrible after all. The motive of the death-wish is a "wish to be rid-of." Death is the simple and practical form in which the "wish to be rid-of" is expressed. It will, however, be readily realised that after the "wish to be rid-of" enters consciousness as a death-wish, the patient may be horrified to find himself possessed of the motives of a would-be murderer. Much of the patient's anxiety can therefore be allayed by the interpretation of this type of dream from its simple wish foundations. To accept the idea in consciousness of the wish to murder a person is a reasonable cause for anxiety, but there is nothing to worry about if the patient realises that he is only anxious to get rid of that person because that person happens to be in the way of his wish-fulfilment.

ANXIETY DREAMS (FEARED BUT NOT DESIRED).

This is a common type of dream, of which probably the most familiar example is that of "missing trains." The dreamer is afraid of his inadequacy and feels incompetent to fulfil the task which lies before him. His dreams express his lack of confidence and fear of failure. A medical student, preparing for an examination, may dream that on the way to the examination hall he misses the train, that when he has caught it, it goes to the wrong destination, that it finally arrives half an hour late, that he has then lost his pen and when the closing hour has struck he is still only half-way through the first question. The feeling tone throughout is one of anxiety owing to a feeling of inadequacy.

TELEOLOGICAL DREAMS.

Dreams, besides referring to the past and present, frequently contain suggestions as to the solution of a patient's difficulties. A woman of 47, wearing horn-rimmed spectacles, a severe expression, and a masculine type of dress, was the headmistress of a large girl's school. She had entered and passed with honours every examination within her power, and judged from one standpoint her life could be measured as successful. As a child her parents had told her that they were bitterly disappointed that she was not a boy and her whole life had been directed towards making up for this unfortunate defect on her part. Up to a point she had succeeded and she had been able to contribute, from very small beginnings, to her parents' comfort in their old age. But she was subject to extreme fits of depression and she was afraid of going out for walks by herself in lonely places, or if it was dark, in case she should be attacked by a man. It was for this depression and anxiety that she came for treatment, during the course of which she had the following dream:

> "I was on the top of a high hill with some other people and I was told that we had to go down and cross the river that lay between the base of the hill and some rugged barren ground on the other side. I did not wish to go and wanted to stay on the hill. I told the others if they went there would be an awful disaster, but in spite of my warning they went down the hill and commenced to cross the river. They had only got half-way across when suddenly there was a terrible storm with rain and wind and they seemed to be washed away. Then I found myself going down the hill and knew that I also had to cross the river, but somehow I did not feel afraid because in my hand I held a talisman. It was circular, like a little box, and I seemed to touch it with my forefinger and then touch my face. With this talisman I was able to cross the river without danger."

She found some little difficulty in evaluating her talisman, until she was asked to make the gesture that she had to make in the dream. There was no doubt about it, and she discovered its meaning for herself. The talisman was a powder-box and puff, symbols of femininity which she had always affected to despise.

SELF-CRITICAL DREAMS.

It is a great mistake to regard the unconscious or its dream activity as being entirely either stupid or evil. This part of the mind is possessed of creative power, a sense of humour, and a vivid artistic and dramatic sense. The critical capacity of the dream consciousness is occasionally devastating and may occur with startling vividness in otherwise uncritical people. For example, a patient entered a consulting room one day, obviously displeased with life. He said he had nothing to talk about and then he admitted that he had had a dream, but said that all dreams were nonsense and that this dream was particularly useless from the point of view of analysis. In other words, his defensive reaction was very strong and was an indication that the dream was likely to be a very fruitful one when interpreted. It was as follows:

> "I was in the corner of a field alongside which was a muddy lane. In front of me was a donkey harnessed in a broken-down little cart, but it had funny legs. They were all twisted like the tendrils of a vine and it looked very unsteady."

The donkey may be taken as a universal symbol in this dream and no experience of dream interpretation is required to understand the self-criticism which it displayed. The patient's association with the donkeys legs was that they were just like the tendrils of a vine which, he explained, could not stand up by itself but required support from something stronger.

REPETITIVE DREAMS.

The repetitive dream is due to a tendency to continue into the dream state the experiences of the previous day. If one has been driving in a car all day, the motion of the car may occupy a prominent part in the dream. Another example is when the mind has been occupied all day with the addition of figures or any work requiring intense application, and continues in the same way in the dream.

INDEFINITE DREAMS.

This last group has been left to contain those dreams which cannot be fitted into the previous categories. It is at least useful as an indication that there are many dreams which we do not understand. Perhaps they are just dream imagination, play without purpose, without meaning in themselves.

Nothing has been said in the foregoing categories with regard to prophetic dreams. Prophesy has always been regarded historically as the main function of the dream as, for instance, in the case of Joseph and the fat and lean kine. It is interesting in this connexion to realise that the measurement of time is a convenient convention on the part of consciousness, which has no existence in the dream state, or in fact at all apart from our consciousness of it. This has been said by some to explain the prophetic nature of dreams, but if there is no time in the unconscious there is at least a difference of before and after, as much as in consciousness. The difference of before and behind, future and past, is independent of any conscious convenience obtained from the time measure. It is probably true that telepathy occurs in dreams, but a claim for anything so remarkable as prophesy should be regarded with a good deal of hesitation. What is certainly the case is that the unconscious, as was said of Manchester, sometimes feels to-day what conscious London is going to think to-morrow. It is therefore obvious that it may be possible to deduce from a dream the course of a patient's subsequent behaviour.

Symptoms.

To complete our understanding of the method in the madness of unconscious processes, it is useful at this point to link up dream formation with symptom formation. It has been said that the dream is the activity of the deeper picture-forming layers of the brain associated with instinctive wishes and fundamental emotional states. The same applies to symptoms. They are derived from the same source, motivated from the same wishes, and cast in the same pictorial and unreasoned mould. The following is an example of such a phobia.

CASE K.—A man, unmarried, aged 37, had a phobia of policemen and begged to be allowed to have a personal interview with the local police inspector in order to find out exactly what it was of which he was being accused. He never passed a policeman without feeling that he was going to be arrested, but he was completely unaware of having ever committed a crime. It was easy to recognise that the policeman was a symbol representing law and punishment, from which it was a short step to deduce the fact that the patient had, at some time, done something of which he felt ashamed. This was discovered by analysis. When he was 3 years old he had been induced to commit an improper practice with an elderly female relative, and had been discovered doing so by his father, who had severely and quite unjustly punished him. From that time he had always felt terrified of his father's presence. The episode had been long forgotten, but the sense of guilt and the fear of punishment had been transferred to the symbol of policemen in general. The situation had been pictorialised and the meaning had been lost in the neurotic's adherence to the form of unconsciously chosen symbolism.

The obsessional case (J) mentioned in Lecture II., was another example of a picture-forming symptom in which the patient gratified the two conflicting wishes in a single obsessional compromise. On a more complex level of behaviour the following case may be cited.

CASE L.—A man, married, aged 30, was under treatment for sexual impotence. In a dream which occurred early in the course of his analysis, he had dreamt that he was standing in the Liberal Club waiting for the entrance of a world-famous politician. He and a few others had just started to sing "For he's a jolly good fellow," when a procession of athletes in shorts and vests filed *smartly* into the hall. These changed from male to female figures in a state of nudity. Interpretation of this dream showed a double tendency in the patient's life to identify himself on the one hand with the successful extraversion of the politician and the athletic prowess of the male athletes, but on the other hand an identification at a deeper level with the feminine sex. The further his analysis proceeded the more examples were adduced of this feminine identification. He wished to be a woman. His analysis had proceeded for a long time when for psychological purposes, he was asked to notice the characteristics of the way in which he shook hands. At first he said this was perfectly normal, but then he realised that he shook hands high up, about the level of his neck holding the tips of the fingers. His first association was that some people had a ridiculous method of an exaggeratedly hearty and dramatic hand-shake. His second association was "I feel if I were to shake hands in the ordinary way down there, there would be a danger of touching one another in the sexual parts." Then he said, "This is what comes *into my mind. If I shake hands in the (h)air it is nearer* my head and therefore away from my sexual feelings. Perhaps this may be an escape." At this stage, it was pointed out to him that although his grammar was usually perfect he had aspirated "air" making it into "hair." He was asked to say what came into his mind with regard to "hair." He said: "I will tell you what *comes* into my mind, but surely it cannot have anything to do with it. I remember when I was about 14, being told by a rather nasty-minded *young* friend of mine of how he *had* sat with a friend of his on the sea front at night with a girl. They had shaken hands with each other inside her knickers." In such a brief *space of time* (about ten minutes in all), it had been possible to arrive at the cause of the manner of the hand-shake. Again he was identified with the girl *of the* episode, and by his first *association* he wished to be touched on the "hair" (sexual), but this wish had been suppressed. The elevated hand-shake was a defence, of course, against the wish to be touched in the region of the pubic hair. As he had said, it was "nearer the head," but the original wish for female identification was fulfilled through the fact, which he readily recognised was quite obvious, that his type of hand-shake was a distinctly feminine one.

Illness, as a whole, needs also to be evaluated from the point of view of its symbolical significance. A patient is not ill for the sake of illness, but for the sake of the value or meaning of illness. The life of the neurotic with its phobias, obsessions, and characteristic behaviour is meaningless when viewed superficially, but when it is interpreted and personally evaluated, it is as full of significance as his dream activities. Behaviour characterised as "simply insane" and therefore judged as meaningless is, in fact, full of meaning if it is regarded as symbolical and purposive. It is not for nothing that the insane patient regards himself as a stone, or Napoleon, or pleads that he is the object of mysterious, external influences. *Insanity, although a mental disorder, is arrived at by an inexorable, ordered and understandable, although unconscious, process.*

Self-knowledge and its Limitations.

The interpretative method can do much to resolve the patient's anxiety simply by exposing the motive and meaning of his apparently disordered and uncontrollable impulses. In particular, a patient with an obsessional psychology always wishes to have everything ordered and simplified. To be possessed of a dissociated impulse, the origin, motive, and meaning of which he cannot understand, causes him acute discomfort and anxiety. An understanding of what is the matter and why it is the matter goes a long way towards allaying both his anxiety and his obsession. This applies also to the anxiety states, where the source of anxiety is unconscious. To know what we fear is bad enough, but not to know what we fear is infinitely worse. Fear that is finite can be fought and faced, but fear that is infinite and indefinite can never be overcome.

Treatment can be carried out by illustration, explanation, and interpretation, but to gain self-knowledge is not always to gain cure. For example, in the case of the man mentioned above who wished to be a woman, it was not sufficient for his cure to know that this was what he wished. His wish to be a woman must cease, or at any rate be modified to such an extent as to be compatible with the ordinary standards of manhood.

The difficult cases to cure are those who do not wish to give up their unconscious wishes when they become conscious. For example, a patient of 27 had spent his whole life contentedly attached to his mother's apron-strings, resorting to invalidism and self-pity when things got difficult. During the course of treatment he realised that what he wanted was a perfect opinion of himself and complete possessive intimacy with his mother, but even when he was conscious of the motive of his illness it still remained as what he wanted. There are many cases which present this difficulty, but a further step may be achieved by helping the patient to understand that even his mother is not the end in herself, but only a means to an end. She is, in fact, only a symbol of his wish for priority, security, and power. To the neurotic the end is always lost sight of in devotion to the means, because the means has become the symbol of the end. It was not really the possession of his mother that he wanted, but that he should be valued, that he should be safe, and that he should feel the strength of his power. These are not essentially neurotic goals. *It is the means by which they are sought, and with which they are confused, that are the characteristics of neurotic behaviour.* It should be possible for such a patient to see that these goals can have a real value and a possibility of real achievement, without necessarily expecting too much either of himself or of life.

SPECIAL ARTICLES

PUBLIC HEALTH IN LOCAL LEGISLATION.

OUR annual survey of recent Local Acts reveals the usual efforts of individual local authorities to improve upon the public health standards applicable to the country as a whole. Several novel clauses have been passed into law, and these will doubtless form precedents to be followed. The Report of the Local Legislation Committee, issued in the past autumn, draws attention in an appendix to various novelties. Unfortunately, the appendix is incomplete; it does not contain references to Scottish local legislation, and it omits such interesting innovations as the radium clause in the Kingston upon Hull Act. Moreover, though sufficient time elapsed between the beginning of August (when the session ended) and the publication of the report to bring the references up to date, the appendix inconveniently makes its references speak to the clauses as numbered in the Bill stage instead of the sections as finally numbered when the Bill became law.

One novel provision, for which Edinburgh seems to have furnished a precedent, concerns the nuisance of noise. A noise nuisance is deemed to exist where any person makes or causes to be made any excessive, unreasonable, or unnecessary noise, and where such noise is (*a*) injurious or dangerous to health, or (*b*) capable of being prevented or mitigated when regard is had to all the circumstances of the case. Newport, Bootle, and Stockton-on-Tees adopted the precedent but with a saving for trading interests, railways, &c., which may diminish its value. The local authorities concerned are empowered to deal with the noise nuisance as they deal with any other nuisance under the general public health law. At Hendon and Rotherham the sabbath calm is not to be broken by the noise of crying or bell-ringing to sell or advertise any article or commodity. This extends a provision against crying newspapers on Sunday which was already familiar—for instance in the Bognor and Chester Acts last year. Another new power concerns the supervision of private schools which a recent London prosecution suggested was inadequate. At Hull, by-laws may secure the proper heating, lighting, and ventilation of premises used as schools not maintained by the corporation, adequate washing and closet accommodation for the children, and facilities for drying their clothes. Interest in the young has prompted Liverpool to take power to regulate the hours of employment, meal intervals, holidays, and general welfare of young persons employed in errand work outside the Factory Acts. Welfare provisions at Cardiff extend certain general provisions (Section 72 of the Public Health Act, 1925) against food contamination so as to apply to rooms within the Factory and Workshop Act and to require adequate water-supply and, if the room is used for preparing food for sale, toilet soap and towels for employees. The supervision of food and food-supply has, of course, been a common feature of Local Acts. Noteworthy enactments in this respect in the past session include Section 59 of the Rotherham Act, forbiding the sale of meat within the borough unless the butcher, merchant, or dealer in meat is registered; no premises are to be used for this purpose unless also registered. Under Section 92 of the Bristol (No. 2) Act punishment awaits the seller of unsound food unless he proves that, at the time of the sale, he and his servants were ignorant of the unsoundness. The Cardiff Act (Section 108) enables the city to decide that nobody but a shopkeeper shall offer meat or "meat food product" for sale from a vehicle, basket, or barrow unless his storage accommodation has been approved and certified. Such accommodation will be registered and subjected to inspection by medical officer of health and sanitary inspector. There is no need to mention familiar clauses as to food storage in dwelling-houses, but Cardiff has now a direct provision that all future dwelling-houses must have a properly ventilated and fly-proof larder. Other usual food clauses are the power to take samples for analysis, the restriction on infected or tuberculous persons handling food, by-laws as to inspection of meat and transport of food, notification of slaughter of animals unfit for food, and prohibition of bringing inedible fats into premises where food is prepared. The accustomed ice-cream and potted meat clauses are frequent; the power to refuse or revoke registration of ice-cream manufacturers and sellers at Darlington, Bootle, and Southport is worth noting. Food poisoning is made notifiable by medical practitioners in 11 localities. Hull continues the national kitchen system, and the Morecombe and Heysham Order authorises municipal contribution towards tanks for cleansing or sterilising mussels.

As regards the treatment and prevention of disease, an interesting Hull provision allows the corporation to subscribe to any trustees or other body holding or supplying radium subject to terms and conditions as to the supply and use of the radium; the expenditure is not to exceed a penny rate. There is additional power at Hull to enable municipal supply to medical practitioners (with or without charge) of medicines, appliances, and requisites for surgical treatment; it seems that the practitioner need not be registered. Infectious diseases provisions as to removal of dead bodies, cleansing filthy premises and articles, compulsory information to the medical officer, furnishing of laundryman's name, notifying the head teacher of a school-child's infection, closing Sunday-schools and entertainments during an epidemic, and so on appear frequently as in former years. There are precautions against plumbism in water-supply, enactments relating to Rochdale, Stockport and Kingsbridge and Salcombe. Veterinary provisions to prevent insanitary conditions in stables go further in several places, and include a power to obtain a demolition order for stables and cowsheds where infectious or parasitic disease has appeared and the premises cannot be efficiently disinfected. The pigeon nuisance is dealt with at Hull and at Croydon.

Housing and drainage matters naturally receive special attention. Cardiff requires that new dwelling-houses must have not only the fly-proof larder already mentioned but also a secondary means of access to a street for removal of house refuse. The Bournemouth Act allows the corporation to provide on the occupier's request a galvanised iron dust-bin on agreed terms. Newport has a similar power with different arrangements for recovering the reasonable cost from the owner or occupier. Birkenhead requires sufficient room to be left near future public buildings, public garages, and warehouses, not only for the arrival of fire engines but also for the storage of dust-bins. To return to Cardiff, boats used for human habitation have there been linked up with tents, vans, or sheds. Such boats are not to be placed on land abutting on a street in advance of the building line, nor in a square, court, alley, or passage to which the public has access and which is required to be left free of obstructions; nor must such boats be placed or kept on land or water adjoining the foreshore without municipal approval, though canal-boats and vessels used for navigation are naturally excepted. At Birmingham, Liverpool, Birkenhead, and Wednesbury a working-class dwelling will be deemed not in all respects fit for human habitation if its owner fails to keep it sufficiently repaired and painted and the interior surface of its walls sufficiently papered or distempered with washable distemper of suitable quality so as to prevent dilapidation and secure reasonable amenities for the occupiers. As for drainage, the rural district councils of Epsom and Guildford, using their new powers under Section 55 of the Local Government Act, 1929, of promoting Bills, have obtained almost identical Acts which inter alia penalise anyone who without consent commences to erect a dwelling-house within 50 feet of a cess pool on land of which he is owner or lessee. The Birkenhead Act (Section 64) forbids the erection of a new building over a drain without consent. Cardiff enacts that anyone who seeks not merely to "reconstruct or alter" a drain (as in Section 39 of the general Public Health Act of 1925) but also to repair a drain must, except in emergency, give 24 hours notice in writing. Epsom and Guildford have taken power to prohibit erection of buildings meant for dwelling houses on land liable to flooding or unsuitable by reason of its subsoil; the restrictive order is subject to approval by the Minister of Health who may hold a local inquiry. Precautions against floods (through the prohibition or regulation of building on low-lying land) also appear in Section 5 and Part XII. of the gigantic consolidation of the London Building Acts on which the London County Council is to be congratulated. Mere amenities are perhaps not strictly a matter of public health, but it is clear that the restriction of advertisements is being tightened in many places, while at Epsom and Guildford trees are to be registered for preservation and protection almost as if they were ancient monuments.

This cursory and disconnected survey of the local legislation of the session 1929–30 gives no complete picture of the corporate activities of our local authorities in a session of exceptional activity in this respect. Ample material for study will be found in the official index to the Local Acts of the session published by H.M. Stationery Office (price 2*s.* 6*d.*) wherein the alphabetical entries range from "Aerodromes, &c., provision of" (at Portsmouth and Liverpool) to "Windows, size and height of" at Aberdeen. The report of the Local Legislation Committee recommends that many clauses which have become common in Local Acts in the past five sessions should now be caught up in a general adoptive Public Health Bill as was done in 1925, and that such a Bill should be introduced without delay. It would certainly be a convenience if the Bill could be passed into law in time for its incorporation in the restatement of public health enactments for which, as we mentioned recently, Lord Chelmsford's committee is to prepare the ground.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

THE SUPPLY OF NURSES.

FACTS about the distribution and availability of graduate nurses in this country have recently been gathered by the Committee on the Grading of Nursing Schools. They find that 54 per cent. of 24,389 graduate nurses who are still active in the profession are engaged in private duty nursing. This sample of nurses is taken from 10 States, and is believed to be representative of the more than 210,000 graduate nurses working in this country. Some 4000 doctors agreed that there is no shortage of nurses. However, the proportion of nurses to population is much less in the rural communities than in the cities. This is no doubt largely due to the greater wealth of city dwellers. The committee state that there is "a real need for the services of graduate nurses with high professional standards of nursing care" in these rural communities.

Since physicians stressed the need for good background and the ability to observe and report symptoms with accuracy, investigation was made into the background and education of American nurses. More than half (56 per cent.) have fathers born in the United States. Of the remainder, far the largest group are daughters of British-born fathers. Less than half of the nurses had completed the four years of high school before they entered the training school. About one-quarter had not passed beyond the first year of high school. Ten per cent. had one year or more of college education. Training schools are increasingly demanding a high school diploma at the present time as an entrance requirement. Even in times of prosperity many nurses are unable to find employment. The present depression finds a serious condition of unemployment.

MEDICAL HISTORY AT A UNIVERSITY.

A short time ago it was decided to add a department for the history of medicine to the Johns Hopkins University in Baltimore. Dr. William H. Welch, who held the chair of pathology in the University for many years with great distinction, was appointed head of this new department with the title of Professor of the History of Medicine, and a palatial library was built in his honour opposite the Johns Hopkins Hospital. The building consists of a large reading room and a fine conference hall in which hangs Sargent's well-known picture of the "Four Doctors." In the upper floor are book stacks, two small lecture rooms, librarian's room, and accommodation for research scholars, while among the book stacks themselves are alcoves for readers. Those engaged in research at the present time are Dr. John Rathbone Oliver and Dr. S. D'Irsay. The library is already well filled with journals and reference books for the history of medicine, and has been enriched by noble gifts from the libraries of Dr. Howard Kelly and other generous donors. It has been fortunate in obtaining the services as librarian of Colonel Fielding H. Garrison, who was for many years in charge of the Surgeon-General's Library at Washington. To inaugurate the library Sir D'Arcy Power, hon. librarian of the Royal College of Surgeons of England, was asked to visit the University in the months of November and December last. During his visit he gave formal lectures on the Principles of Medical Biography, Medical Bibliography, Medical Iconography, and on the growth of an English medical institution, taking the history of St. Bartholomew's Hospital as an example. He also gave a series of informal talks to small groups of students who were interesting themselves in the history of medicine. It will thus be seen that the study of history is becoming a well-recognised and well-endowed branch of medicine in the United States. Lectures are being given at Baltimore by Colonel Garrison and Dr. Oliver throughout the winter session and are attended in each case by classes of 30 to 40 students. The lectures are made practical by teaching students not only the history of the subject but the method of writing critical reviews of current works and biographies of medical personalities of all countries. Each student is allowed to select the subject in which he is specially interested and his essay is expected to show the *Quellen* with a bibliography. Dr. MacCallum, the professor of pathology, has already introduced a similar system in his department.

CRIMINALS AND MEDICAL SECRECY.

In a country where both private and police use of revolvers is still not uncommon, doctors are often confronted with gunshot wounds of questionable origin. Is it the doctors duty discreetly to cloak his curiosity and to take no notice of the nature of the injury apart from his professional care? The physicians of Essex County, New Jersey, believe not. They have voted to report to the police, immediately after treatment, all wounds which they suspect to be the result of criminal acts. Their resolution states that they regard this as a public duty on all fours with the reporting of contagious disease. The Department of Public Safety has agreed to regard such reports as confidential and to use them in evidence only with the consent of the doctor who makes the report.

MEDICAL ECONOMICS IN WEST VIRGINIA.

Some interesting figures have been produced by the West Virginia Medical Association, based on the results of a questionaire study of the incomes of its members. The highest income was $28,000 per annum. Two doctors reported this figure: one a surgeon and the other a general practitioner. The smallest income was $420—that of a physician in a rural community who has been in active practice for 24 years. The "average" West Virginia doctor collects 79 per cent. of his accounts. The average net income of a county general practitioner is $4396, and of the city general practitioner, $6528. The physician working under "contract" earns less—$4166. It was estimated that it requires at least three years for the young doctor to establish himself in the community. The 1500 doctors in the State collect ten million dollars yearly, of which eight million represent net income. Their charity work is valued at one and a half million dollars.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

THE HEALTH OF BELFAST.

THE Belfast annual report for 1929, which has lately been issued, shows a birth-rate of 21·4 per 1000 (22·5 in 1928) and a death-rate of 15·6 (14·0 in 1928). The increase of deaths is attributed to a severe influenza epidemic during the first quarter of the year, when the death-rate was 26·8. The mortality from cancer was 1 per 1000, and from pulmonary tuberculosis 1·16. Details are given of the end-results of pregnancy in 1869 tuberculous mothers. Ninety per cent. of them were delivered of a living child at full term, 2 per cent. of a dead-born child at full term, and 8 per cent. miscarried. Of 696 children born of 291 tuberculous mothers, 512 are healthy, 47 delicate, 11 tuberculous, and 126 are dead.

A study was made of the social condition of those who live in overcrowded conditions, and it was found that: (*a*) the overwhelming majority of people living in overcrowded houses or rooms were *employed*; (*b*) the rents were very low; (*c*) the wages were often —but not by any means always—poor. The deduction to be drawn from the economic point of view is that if the corporation builds houses for "the overcrowded" money will be dropped, for this type of worker will not go into more roomy houses except at a rent economically impossible.

A large part of the report deals with infant mortality, the rate for Belfast being 112 in 1929. More antenatal centres are required. Of 8987 expectant mothers, 1822 received attention at three hospital antenatal centres. It is not possible to state how many of the remainder received antenatal care from their private medical attendants, but the medical superintendent officer of health states that he is advised that probably 70 per cent. are not receiving antenatal examination and supervision. This serious state of affairs can only be met by educating people up to the great need there is for such attention. Future mothers as well as existing mothers should be taught mothercraft; the mother's is a skilled trade. Additional health visitors for maternity and child welfare work are required, and dinners should be provided for poor expectant mothers at various centres.

More than four-fifths of the daily supply of milk to the city is produced in farms outside the city, and over these dairy farms the officers of the city have no supervising powers. Of the milk sold in Belfast 4·1 per cent. of 875 samples were proved to be infected with tubercle bacilli. About 30 per cent. of the dairy cattle in Northern Ireland react to the tuberculin test. By adopting the legislation in force in England a more satisfactory method of dealing with milk-supplies would be found, and it is sincerely hoped that the Government of Northern Ireland will adopt or improve upon the Milk and Dairies Consolidation Act, 1915.

The annual report of the Registrar-General for Northern Ireland for 1929 shows a birth-rate of 20·4 per 1000 of the estimated population and a death-rate of 15·9. The death-rate from tuberculosis is still steadily declining, and is the lowest yet recorded; a slight increase in deaths from cancer is reported. Of the 25,410 children born, 2174 died under 1 year of age.

VITAL STATISTICS OF THE FREE STATE.

The annual report of the Registrar-General of the Irish Free State for 1929 estimates that the population of the State in the middle of the year was 2,946,000. The figure given by the census of 1926 was 2,972,802. There is an increase in the number of deaths as compared with 1928, and a decrease in the numbers of births, of marriages, and of emigrants. The deaths represented a rate of 14·59 per 1000 of the estimated population, the total number of deaths being 42,991. Of the causes of death heart disease is placed highest with 5616; tuberculosis next with 3875; followed by cancer with 3116; and influenza 1659. There has been an increase in the number of deaths by violence from 883 to 971; this increase is mainly due to two distinct causes—the increase of deaths from motor accidents, and an increased number of suicides. The total number of deaths from all forms of vehicular transport increased from 150 to 200, the number of suicides from 98 to 111. Up till recently suicide was uncommon in Ireland, but it appears to be taking a place among the considerable causes of death. The mortality from tuberculosis continued to show a gratifying decline. In 1919 the number of deaths from tuberculosis was 5839, and in 1929 was 3875, almost every intervening year showing a fall. The deaths from cancer are 74 fewer than in 1928. The infant mortality was 70 per 1000 births. The birth-rate shows a decline when compared either with the rate in 1928 or with the average in the ten years 1919–28. In the period 1911–15 the birth-rate was 24·9 per 1000 of the population; in 1924–28 it was 20·57; in 1929 it was 19·78. Illegitimate births constituted 3·2 per cent. of the total. The mortality among illegitimate children was appallingly high; no less than 29·4 per cent. died within the first year of life—a mortality more than four times the general infant mortality. The net emigration for the year —18,145—was the lowest on record, the average for the period 1911–26 being 26,946. Nevertheless, i was more than enough to counterbalance the natura increase of population, or excess of births over deaths

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

A DISCIPLE OF ZEILEIS.

ABOUT a year ago the Zeileis affair apparently ended with the acquittal of Prof. Lazarus of Berlin who published defamatory articles stating that th Zeileis method of treatment is devoid of scientifi foundation, that his diagnostic rod is an absurdity and that the whole business does nothing but mislea the suffering public and prevent them getting regula medical treatment which might cure their ailments Zeileis sued Lazarus before the Vienna Court, but th decision went against him and he had to pay costs But this verdict by no means put a stop to the mas migration to Gallspach, the nest of the "wonde doctor." It seemed that the number of his patient even increased, if we may judge by the fact tha early last summer the Zeileis Institute sent ou printed circulars to all inquirers telling them that a accommodation in Gallspach and the neighbourin towns and villages was booked until October. I fact, the Zeileis business enjoyed such a boom tha the old "master" found the time ripe to drain o his vast clièntele and establish branch offices i adjacent countries, where he appointed regularly qualified doctors who took a course of his method The latest institute has been opened in Budapes by Dr. Paul Tóth, a physician and also a Member o Parliament. His enterprise has caused consternatio in medical circles, and the board of the Medica Association has informed him that it does not hold it compatible with the vocation of a conscientiou physician to apply the so-called Zeileis method Dr. Tóth, replying in a daily newspaper, says hi conscience is clear. He has spent a long time in the Gallspach Institute, and the surprising results see there have made him a zealous adherent. Thousands and thousands, he says, owe their health, their life to the method, and in his opinion the help and cure of sufferers is what really matters and not the rationale of the treatment according to accepted scientific tenets. The Medical Association, which has no disciplinary right over its members except exclusion, will deal with the case at a special meeting.

A TREATMENT FOR LATE SYPHILIS.

At a recent meeting of the Budapest Royal Medical Society Dr. Ödön Rajka read a paper on the effect of light treatment and autohæmotherapy on cases of late syphilis which had already been subjected to "chemo-specific" treatment, but had persistently positive Wassermann reactions. His method, he said, was to give a course of 30 irradiations and 20 injections of blood taken from the patient's own vein half an hour after irradiation begins. The positive Wassermann reactions became negative in 57 per cent. of the latent or symptomless cases, and in 28 per cent. of those in which there were signs of damage to the nervous system. The reaction has so far remained negative for periods of 2–36 months, becoming positive again in about a third of the cases. The subjective symptoms improved in every case (41) of syphilis of the nerve and blood system. The tests were begun two years ago and remissions have varied from 1 to 19 months in length. There has been relapse in nine cases only, and of these four improved on a second course of treatment. The patients all felt better in general health, not only during but also after treatment. They slept and ate better, gained in weight, and became more vigorous. It is probable, Dr. Rajka says, that occasional courses of treatment will stabilise this improved condition.

AUSTRALASIA.

(FROM OUR OWN CORRESPONDENT.)

A REPORT ON HOSPITALS.

PERHAPS the most interesting part of the recent report of the Royal Commission on Hospitals in Queensland is the section on the finance of public hospitals. The Commission recommends the creation of a hospital fund by the collection of a special hospital tax of 1*d.* in the £1 on wages, salaries, and income, with exemption for people with not more than £1 per week. It is proposed that 80 per cent. of any deficiency between the estimated expenditure and estimated income of hospital boards should be paid from this fund, while the remaining 20 per cent. is found by local municipal or shire authorities. It is estimated that such a tax on the population of Victoria (900,000) would bring in about £260,000 a year. In 1928–29 the total annual expenditure of both district and voluntary hospitals in Queensland was £668,596, while their receipts amounted to £258,632, leaving a deficit of £409,964 to be provided from taxation and other sources.

The number of public hospitals in the State is 118, with 4229 beds. Under the Hospitals Acts of 1874 to 1891 the 74 voluntary hospitals receive a Government subsidy of £2 for every £1 obtained from voluntary contributions. (This rate has recently been reduced to £1 15*s.* to £1.) The 44 "districted" hospitals are governed by the Hospital Acts of 1923 to 1929 and include most of the larger institutions. Sixty per cent. of their deficiency between estimated expenditure and estimated receipts is made up by Government grant and 40 per cent. by the local authorities who levy a special hospital tax on the unimproved capital value of the land in their area. This hospital tax the Commission regards as inequitable. The effect of direct taxation in drying up voluntary subscriptions was carefully considered but, while recommending with reluctance any interference with philanthropy, the Commission thinks that the present injustice should not be allowed to continue, and points out that in any case benevolence, as far as hospitals are concerned, is rapidly dwindling. The necessity for stability of hospital finance is all-important.

Friendly Societies.—It was realised that the friendly societies members, by contracting for domiciliary medical service, relieve to a large extent the pressure on the public hospitals. It was also realised that, if a wage tax were imposed, members of friendly societies would have to bear a double burden, and to overcome this the Commission recommends provisionally that members of these societies be provided with intermediate ward accommodation at the rate of 9*s.* per day which is the maximum charge for public wards. They would have the right of attendance by their own doctor in the hospital.

Central Hospital Commission.—The Commission has come to the conclusion that hospitals throughout the State could be most effectively managed by a central hospital commission consisting of three members, including a permanent full-time chairman. Among other duties it would make a hospital survey of the State, coördinate the hospital system, standardise hospital expenditure, and make more effective the combined activities of the health department and the public hospitals.

Intermediate and Private Hospital Accommodation.—Although in agreement with the establishment of intermediate wards in public hospitals wherever the conditions are favourable, the Commission thinks that hospital authorities should concentrate on the efficiency and adequacy of their public ward accommodation before contemplating the introduction of intermediate wards. To such wards patients would be admitted on payment of the full charge for maintenance and nursing attendance. The wards should be under the control of the medical superintendent; but the patients would have the right to choose their own medical attendant and make their own arrangements about his fees.

Contributory Schemes.—A source of income which has been of great value to hospital boards throughout the State has been the group contributory schemes, whereby for 6*d.* or 1*s.* per week the contributor and his dependants are provided with hospital accommodation when required. The Commission recommends that such schemes should be encouraged. In order to prevent abuse of the scheme, it is suggested that the income limit for single men or women should be £260 per annum and for a married man £340 per annum. The main difficulty with these schemes from the point of view of the medical man is that while the hospital service is thus contracted for, no definite statement is usually made about medical attendance, and most contributors are under the impression that the weekly payment entitles them to free medical attendance in hospital as well. Such a misconception has been the cause of a certain amount of unpleasantness, but with a strict control of the income limit and a clear statement to the contributor as regards medical attendance, the extension of the group system should be satisfactory.

Medical Representation.—It is proposed that a doctor, disassociated from the public service, and nominated by the medical profession in the area, should be appointed to the boards of hospitals in Queensland of more than 100 beds.

Infectious Diseases.—At present the whole financial burden of the treatment of infectious diseases is placed upon local municipal or shire authority. It is considered that the outlook has been much altered in late years by the appreciation of the influence of "carriers" on the spread of infectious diseases. In years gone by, when these arrangements were made, it was held that the chief causes of the spread of infectious diseases were faulty sanitation and cleansing. The Commission now recommends that infectious diseases should be a charge on hospital boards. Local authorities will be subject to their proportion of the local hospital boards deficit, and this, it is thought, should be a sufficient monetary liability to guarantee the area being kept clean.

Nursing.—In the interests of patients and to facilitate the training of nurses, it is proposed that the hours of duty of the nursing staff should be increased from 44 hours per week to 48 hours per week, exclusive of meal hours.

Patients' Visitors.—As an unobjectionable method of raising money, the Commission suggests that each visitor to the patients in the wards, in excess of two, should be required to contribute 6*d*. On admission to the hospital, the patient is given two free passes which he can give to his relatives or friends. Any visitors beyond this number are charged. This system has been in use in the Victorian public hospitals for many years. The Melbourne hospital (590 beds, including the convalescent hospital) derives a yearly revenue of over £4500 from this source.

MEDICINE AND THE LAW.

Doctor and Barrister: No Fusion.

THE annual statement of the Bar Council contains, as usual, a summary of the rulings given during the past year on questions of professional etiquette affecting barristers. A member of the medical profession, it seems, asked the opinion of the Bar Council on the following question. If called to the Bar, would he be allowed to practise as a barrister while continuing his existing practice in the medical profession? The Council in reply referred to the principle that a practising barrister should not, as a general rule, carry on any other profession or business; they grimly added that, whatever might be the exceptions to this general rule, the case under consideration would not be an exception to it.

The known disinclination of the Bar to allow its members to practise any other vocation is illustrated by another ruling in the annual statement. A barrister who is also a rating surveyor and valuer sent out circulars on letter paper on which he was described as "Rating Surveyor and Valuer, Barrister-at-law," inviting persons to employ him on appeals against their assessments. This was a threefold breach of professional etiquette. First, a practising barrister should not also practise as a surveyor and valuer; secondly, he must not print the words "barrister-at-law" on his note-paper; and, thirdly, he must not ask for work. The Bar Council remarks that, as letters addressed to the offender failed to obtain an answer, the matter was reported to the Bench of his Inn. This incident shows how easily the traditions of the Bar can be embarrassed by association with some other calling. The medical and legal professional standards are, of course, similar as respects advertising and touting, but there are a few practical differences which might cause awkwardness in the event of an attempted fusion of the two vocations. The Bar does not allow its practising members to state after their names on the doors of their chambers in the Inns of the Court even the rather scanty references to professional qualifications which are permitted on the doctor's brass plate. The Bar does not allow partnerships. The barrister is immune from actions of professional negligence. *The double qualification (in both medicine and law)* is naturally of great value to a man practising either medicine or law. Indeed, Parliament may some day enact that all coroners should possess this duplicate training. But the Bar will not allow the practising medical practitioner to practise also as a barrister, though it is not clear that the General Medical Council would object in the converse case.

Proof of Relationship.

The objection to the admission of hearsay evidence is a well-known feature of English law. Sometimes however, necessity compels a compromise with the principle. In criminal proceedings before Mr. Justice McCardie at the end of last year, it was essential for the prosecution to prove that two persons were brother and sister. The prosecution tendered the evidence of a witness who said he had always regarded them as such. Counsel for the defence objected that this was mere hearsay and must be rejected. The judge admitted the evidence. To hold it hearsay, he is reported to have said, would be to destroy all the laws of evidence. A man could not know his mother because he could not personally remember his own birth; a father would not be able to say "this is my son" unless he had been present at the birth. In spite of these judicial dicta, it might be more frank to say that such evidence is admitted of necessity because the facts cannot otherwise be established. In genealogical cases the evidence of entries in the family Bible or of tombstone inscriptions is admitted partly on the ground that publicity supplies the want of connexion between the entry or inscription and the particular individual. There is a presumed absence of any interest to misrepresent the truth; it is also presumed that the person who made the entry or ordered the inscription had peculiar means of knowing the facts; in the background somewhere, too, there is probably the feeling that a decision on the available information is necessary and that the information is not available in any other form. But such information will not be allowed as evidence on a question of relationship in non-pedigree cases—e.g., on the question whether two persons are brother and sister under Section 3 of the 1908 Act for the punishment of incest.

ENLARGEMENT OF CHIPPENHAM HOSPITAL.—Last week Lady Margaret Spicer laid the foundation-stone of an extension of this cottage hospital which is to cost about £5000. The enlargements include new men's and women's wards, of eight beds each, two private wards, nurses' quarters, an anæsthetic room, and improvements in the theatre.

EXTENSION OF NEWCASTLE VICTORIA INFIRMARY.—Sir Walter Runciman last week opened a new "Runciman Wing" of the nurses' home at this hospital and announced his gift of £25,000 to the appeal fund of the institution. The wing provides accommodation for 150 nurses. The extension fund, to which Sir Walter Runciman had already given £50,000, had previously reached £113,000. The entire cost of the scheme is estimated at £164,000.

THE DISTRIBUTION OF RADIUM.

I.—IN LONDON.

King Edward's Hospital Fund has at its disposal 10 grammes of radium to lend to London hospitals; nearly one-half of this was the gift of the late Sir Otto Beit, the remainder being purchased through special donations and through money received from the National Thank-offering Fund earmarked for radium. Four grammes were distributed among twenty hospitals during 1929 and by arrangement with the National Radium Trust 4 more grammes have been exchanged for their equivalent in the form of a "bomb," which is on loan with the Westminster Hospital. Last autumn a further allocation of 2 grammes was made among seven hospitals as follows:—

	Milligrammes.
Westminster Hospital	250
St. Bartholomew's Hospital	450
Middlesex Hospital	370
London Hospital	250
Marie Curie Hospital	250
Royal Free Hospital	200
Chelsea Hospital for Women	100

making a total of 1870 mg. and leaving 130 mg. as a margin required by suppliers. Three of these hospitals had participated in the previous distribution to twenty hospitals and four had not. Of these allocations 950 mg., in addition to the "bomb," have already been delivered to the hospitals concerned, while specifications have been received for nearly the whole of the balance. Summarised briefly, the position is that 10 grammes have been allocated among twenty-four hospitals, and 9 grammes have been delivered and are in use at twenty-three hospitals.

The following is the list of the twenty-four participating hospitals:

A = Amount of radium allotted by King's Fund.
B = Amount of radium held by these hospitals, including King's Fund allotment (approx.).

	A	B
	Milligrammes.	
Hospitals with Medical Schools:		
Charing Cross Hospital	250	250
Guy's Hospital	500	500
London Hospital	250	2,000
Middlesex Hospital	870	1,900
Royal Free Hospital	200	700
St. Bartholomew's Hospital	450	2,000
St. George's Hospital	150	350
St. Mary's Hospital	150	300
St. Thomas's Hospital	150	500
University College Hospital	500	700
Westminster Hospital	4,250	5,000
Other General Hospitals:		
Prince of Wales's General Hospital	150	150
Queen Mary's Hospital for the East End	150	150
Royal Northern Hospital	150	250
West London Hospital	150	150
Special Hospitals:		
Central London Throat, Nose, and Ear Hospital	100	100
Chelsea Hospital for Women	200	350
Elizabeth Garrett Anderson Hospital	150	150
Golden Square Throat, Nose, and Ear Hospital	150	150
Hospital for Women	100	250
Marie Curie Hospital	500	700
St. Mark's Hospital for Fistula	100	250
Samaritan Free Hospital for Women	100	350
South London Hospital for Women	150	150
	9,870	18,850
Margin required by suppliers	130	
Total King's Fund Radium (mg.)	10,000	

The total amount of radium available at the voluntary hospitals in London is, of course, in excess of the figure given above.

In the allocation of radium the Distribution Committee of King Edward's Fund had regard to the competence of the staffing and equipment of the hospitals concerned, preference being given to those in which the cure of disease was associated with keen interest in the furtherance of knowledge. Reasonable provision having been made at the first allocation for general and urgent needs, more weight was given at the second to the policy of concentration at radium centres.

II.—IN THE PROVINCES.

In August, 1930, when the Radium Commission presented its first annual report, a total of 18 grammes of radium had been provisionally allotted to national centres, although only 8 grammes had been actually delivered. It was, however, anticipated that the whole 18 grammes (including the 4-gramme bomb) would be in full clinical use by the end of the year. Of this amount 4 grammes was allotted to the National Post-Graduate School thus:—

Mount Vernon Hospital (for clinical work)	3 grammes
Radium Institute (for radon)	1 gramme

Distribution of the remaining supply of radium has been restricted to 7 centres in England, 4 in Scotland, and 1 in Wales, which possess a University with a medical school and complete clinical courses, and in which one hospital nominated by the local medical faculty has been recognised as a national centre. When the report named was issued the distribution to these centres had taken effect as shown in the following Table:—

National radium centres.		Milligrammes of radium.			
University.	Approved hospital.	Previously in hand.	From Radium Commission.		Total from all sources.
			Received.	To come.	
Aberdeen.	Royal Infirmary.	250	250	500	1,000
Birmingham.	General Hospital.	600	950	500	2,050
Bristol.	Royal Infirmary.	176	—	1,500	1,676
Cardiff.	Royal Infirmary.	115	500	—	615
Dundee.	Royal Infirmary.	586	500	—	1,086
Edinburgh.	Royal Infirmary.	600	500	900	2,000
Glasgow.	Western Infirmary.	300	705	1,295	2,300
Leeds.	General Infirmary.	500	—	700	1,200
Liverpool.	Royal Infirmary.	Not stated.	—	1,000	1,000 plus.
Manchester.	Royal Infirmary.	Not stated.	770	980	1,750 plus.
Newcastle.	Royal Victoria Infirmary.	Not stated.	325	835	1,160 plus.
Sheffield.	Royal Infirmary.	334	—	665	334
—	—	3,461 plus.	4,500	8,875	10,671 plus.

At four centres—Aberdeen, Birmingham, Bristol, Newcastle—500 mg. of the radium is to be used for making radon.

ROYAL AUTOMOBILE CLUB HOSPITAL FUND.—About 18 months ago this club established a fund for the benefit of hospitals which deal with a large number of cases arising out of motor accidents. Since the Road Traffic Act now makes it obligatory for insurance companies to pay to hospitals a sum not exceeding £25 in cases where a third party has received treatment following a motor accident the fund has been wound up and the balance in hand divided among the hospitals which had been benefiting by the arrangement.

PUBLIC HEALTH SERVICES

SCHOOL MEDICAL SERVICE IN IRELAND.

THE establishment of a school medical service[1] was authorised in Ireland in 1919, but its inauguration has been delayed until it could be combined with the appointment of county medical officers of health so that the chief school medical officer and the medical officer of health should be one and the same person. This policy has been justified and has secured continuity of treatment for the child from infancy until it leaves school.

Medical inspection is now in operation in Dublin and Cork County Boroughs, Clonmel, and in the counties of Cork, Kildare, Offaly and Louth, and it is to be started in many of the other counties as soon as possible. It has revealed a high rate of decaying teeth, enlarged tonsils and adenoids, and defective vision, but less crippling and tuberculous deformity than was expected. Dental caries was noted in more than half the children examined; enlarged tonsils and adenoids in 18 per cent., and defective vision in 11 per cent. Defects of eyes, ears, teeth, and throat and minor ailments are treated under the scheme; full use is made of existing facilities in hospitals. Orthopædic treatment is not at present an integral part of the scheme but special attention is given to the correction of deformities.

A somewhat high percentage of uncleanliness was found, but in Cork county borough, where a scheme of school medical service has been in operation for six years, the figure dropped from 20·3 per cent. in 1926 to 12·9 per cent. in 1928, while the percentage of under-nourished children is also steadily diminishing. This improvement is attributed to the work of the school nurses in educating parents and following up children treated for septic teeth and tonsils. It has been found that in county areas this work can best be done through the agency of the District Nursing Association. The nurse from this body has known the child from its infancy and has already gained the confidence of the parents. There are now 140 nurses affiliated with the Queen's Institute of District Nursing, and new districts are being opened up.

On the whole the hygienic condition of the schools is below the standard desired, and the equipment is often found to be obsolete. Hot midday meals are provided at an increasing number of schools.

MENTAL HOSPITAL REPORTS.

THE *East Sussex County Mental Hospital* at *Hellingly* had 1255 patients on its books on the first day of last year. The recovery-rate was 38 per cent., a distinct improvement on the previous year, and the death-rate 7·98 per cent. Post-mortem examinations were made in 70 per cent. of the cases. Of the 141 patients discharged during the year, 48 were sent out on trial before discharge, and 29 of these had a money allowance. The Mental After-Care Association has, as usual, done invaluable work for the discharged patients. The system of parole has been extended; 9 men are allowed out of the grounds and 53 men and 129 women are free within the estate. There was a severe epidemic of influenza in the spring, followed by 29 deaths from pneumonia. There were 11 cases of dysentery, some of which were only diagnosed bacteriologically. Four patients died of general paralysis; three of them had been treated with malaria but it had always been doubtful whether they were not too advanced for the treatment to be any good. The ophthalmic and dental surgeons attended regularly, and six major operations were performed. Special attention has been given to occupational therapy and classes are held in almost all the female wards. An attempt has been made to ameliorate the condition of the post-encephalitics, but without much result. Malarial treatment has been continued and a summary of the results is published in this report. The pathologist puts forward a special report of his routine work, public health work for the county, and research work. He discusses uræmia as a cause of death in the insane. He says that he has come to the conclusion that the mental patient is insane because his bacterial resistance is low, and he therefore stresses the importance of treating focal sepsis. There has been an increase in attendance at the out-patient clinic at Eastbourne, 32 new patients having been seen during the year. There is still a shortage of nurses, although everything possible is done to make the staff happy and comfortable. Two nurses passed the State examination and four attendants and eight nurses obtained their R.M.P.A. certificate, for which training is compulsory at this hospital.

At the *Inverness District Asylum* there were 749 people on May 15th, 1930. The recovery-rate for the year was 37 per cent. and the death-rate 7·5 per cent. The general health was good except for ten cases of scarlet fever in the autumn. The institution is overcrowded and the sleeping accommodation for nurses is inadequate. The medical superintendent discusses the future of the asylum in a memorandum and urges the provision of a nurses' home, which would make it possible to provide such essentials as dental and actinotherapy departments, and an isolation hospital. Farm and garden gave a good yield, in addition to providing occupation for many of the patients. During the year three nurses and one attendant gained the R.M.P.A. certificate.

The *Stirling District Board of Control* had 987 certified and 25 voluntary patients in residence on May 14th, 1930. The recovery-rate was 37·3 per cent. and the death-rate 8·4 per cent. Sixteen patients were sent out on trial before discharge. Acute mental ailments preponderate among the admissions and are treated on the verandahs of the reception hospital. The steadily increasing admission-rate is giving rise to some anxiety as to accommodation. The health was good throughout the year, except for some mild influenza. General paralysis was treated by induced malaria and by tryparsamide. In the electrotherapeutic department 136 patients were treated and 26 more had diagnostic X rays. The dental surgeon visits weekly and submits a report of the 218 patients he examined. Occupational therapy is enthusiastically carried on, and the dairy, farm, and garden provide outdoor employment as well as milk, vegetables, and fruit to improve the dietary. The laundry has been brought up to the most modern standard. During the year six nurses and four attendants obtained the R.M.P.A. certificate

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 3RD, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 164 (last week 135); scarlet fever, 1854; diphtheria, 1430; enteric fever, 29; pneumonia, 1757; puerperal fever, 43; puerperal pyrexia, 101; cerebro-spinal fever, 19; acute poliomyelitis 3; acute polio-encephalitis, 2; encephalitis lethargica, 9; continued fever, 1; dysentery, 25; ophthalmia neonatorum, 97; and plague, 1. (Port of Bristol.) No case of cholera or typhus fever was notified.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 6th–7th was as follows: Small-pox, 224 under treatment, 4 under observation (last week 218 and 3 respectively); scarlet fever, 1688; diphtheria, 2013; enteric fever, 18; measles, 83; whooping

CORRESPONDENCE

A RESEARCH INSTITUTE FOR SURGEONS.

To the Editor of THE LANCET.

SIR,—With reference to your leading article of Jan. 3rd we should like to call attention to the fact that while England may lack an institute where surgeons can carry out experimental research bearing on their art, this does not apply to Scotland. In Edinburgh University, the surgical unit under Prof. D. P. D. Wilkie is equipped precisely for such work as is referred to, and for several years a large team of surgeons has been engaged in solving surgical problems by work carried out simultaneously in the wards of the Royal Infirmary and the experimental laboratories of the surgical research department of the University. We have been frequently told by leading surgeons from abroad that this centre for surgical research is one of the greatest in the world at the present time.

We are forwarding this letter because we believe that your readers should be made aware of these facts. We are, Sir, yours faithfully,

STANLEY DAVIDSON, B.A., M.D., F.R.C.P.,
Regius Professor of Medicine, University of Aberdeen.
J. J. R. MACLEOD, M.B., D.S.C., F.R.C.P., F.R.S.,
Regius Professor of Physiology, University of Aberdeen.

Physiology Department, Marischal College, Aberdeen.
Jan. 8th, 1931.

CŒLIAC DISEASE.

To the Editor of THE LANCET.

SIR,—Prof. Leonard Parsons is in slight error in ascribing to me the suggestion that cœliac disease may be due to obstruction of the lacteals by *tuberculous* disease (THE LANCET, Jan. 10th, p. 64). In my paper on Fatty Stools from Obstruction of the Lacteals[1] to which he presumably refers, my conclusion was that "the inability to absorb fats in cœliac disease, and the attendant complications, such as infantilism and tetany, can best be accounted for by an obstructive lesion (probably infective in origin, as the disease is acquired and not congenital) of some part or parts of the lacteal tree." I did not suggest that the infection was tuberculous. I still think that this hypothesis is a very reasonable one, and the more so because it is now generally agreed that the disorder is one of absorption and not of digestion, and because no disease of the only other part of the absorptive system (namely, the intestinal mucosa) has been demonstrated. In the paper referred to I drew attention to the remarkable resemblance in the clinical symptoms and stool analyses in patients suffering from cœliac disease, sprue, and tabes mesenterica with obstruction of the lacteals, and described two cases of the last-named condition in which the lacteals were shown in the course of a laparotomy to be enormously over-distended with chyle. In all three of these conditions we have abdominal distension, bulky fatty stools, similar fæcal analyses, tetany, and other evidences of calcium deficiency.

At first, I believe, physicians for tropical diseases (like the pædiatrists in the case of cœliac disease) were unwilling to accept my hypothesis that an inflammatory obstruction of the lacteals was a part of the pathology of sprue. I was greatly interested, therefore, by a letter from Colonel Davenport Jones[2] in which he described, quite independently, the same distension of the lacteals seen by him during laparotomies for appendicitis in two cases of tropical sprue. This over-distension of the lacteals with fat is presumably an affair of active life when more or less normal food is being ingested. The failure to discover it at necropsy is of no significance. Someday a case of cœliac disease will develop appendicitis, and then I shall not be surprised to learn that the lacteals were found to be over-distended with fat droplets just as they have been shown to be in occasional cases of tabes mesenterica and sprue. In the meantime no fatal case of cœliac disease can be regarded as having had a full investigation unless this includes a careful inspection and microscopical examination of the thoracic duct, the receptaculum chyli, the lacteals, and the mesenteric glands. I am not convinced that a successful injection of the system after death with methylene-blue and in a reverse direction can be held as proof of its functional efficiency during life. The morbid anatomy of the living is sometimes very eloquent.

I am, Sir, yours faithfully.

Wimpole-street, W., Jan. 11th, 1931. J. A. RYLE.

ACUTE MYELOGENOUS LEUKÆMIA.

To the Editor of THE LANCET.

SIR,—Dr. Knyvett Gordon pleads for the publication of more cases of acute myelogenous leukæmia. Here is one which has just been under my care at the London Hospital.

The patient, a married woman of 35, previously of good health, was admitted suffering from profuse hæmaturia which had set in suddenly and without pain three days before. Coincidentally with this bruises had appeared on the legs. On examination she was pale but did not seem very ill and the temperature was only slightly elevated. The urine was full of blood and there were large bruises and a few petechiæ on the legs. The mouth and pharynx showed nothing abnormal and the spleen and superficial glands were not palpable. The blood contained 4,000,000 red cells per cubic m.m., 65 per cent. of hæmoglobin, and 82,000 white cells, of which 80 per cent. were myeloblasts. She went rapidly downhill. The

[2] THE LANCET, 1924, ii., 525.

(*Continued from previous page.*)

cough, 125; puerperal fever, 24 (plus 7 babies); encephalitis lethargica, 120; poliomyelitis, 2; "other diseases," 57. At St. Margaret's Hospital there were 15 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were no deaths from small-pox, 3 (1) from enteric fever, 62 (1) from measles, 16 (8) from scarlet fever, 26 (3) from whooping-cough, 43 (5) from diphtheria, 53 (10) from diarrhœa and enteritis under two years, and 60 (11) from influenza. The figures in parentheses are those for London itself.

As in the previous week, there were 17 deaths from measles at Liverpool. Hull reported 11, Bristol, Birmingham, and Newcastle-on-Tyne 4 each, and Rhondda and Swansea 3 each. Eight fatal cases of diphtheria were reported from Liverpool, 3 each from East Ham and Birmingham, and 2 each from Leyton, Portsmouth, and Hull. Diarrhœa caused 7 deaths at Manchester, 4 at Liverpool, and 3 at Birmingham.

The number of stillbirths notified during the week was 311 (corresponding to a rate of 42 per 1000 births), including 50 in London.

temperature rose higher, the liver became considerably enlarged, and the spleen palpable. The mouth and pharynx remained normal, but profuse hæmorrhage from the urinary tract continued and she died five days after admission or just eight days from the onset of the illness.

I agree with Dr. Gordon that sepsis is a result and not a cause in this disease and the absence of any signs of it in the above case bears out this view.

I am, Sir, yours faithfully,
ROBERT HUTCHISON.
Devonshire-place, W., Jan. 10th, 1931.

TREATMENT OF LOBAR PNEUMONIA.

To the Editor of THE LANCET.

SIR,—In view of the interest aroused by the reports on the serum treatment of lobar pneumonia (THE LANCET, Dec. 27th, 1930, pp. 1387 and 1390), one of which emanated from Glasgow, it has seemed to me worth while to make a note on a series of untyped pneumonias, treated on orthodox non-specific lines.

The cases under review are those treated in a ward reserved for male pneumonia, and which receives all cases over 6 years of age. They comprise all such cases admitted during the calendar year 1930, which proved to be true lobar pneumonias. In all 233 cases were treated, and out of that number there were 37 deaths—a case-mortality of about 15·9 per cent. An analysis of these 37 deaths shows that 29 patients died from the usual complications—viz., failing heart and anoxæmia. One of them had a bilateral lesion. Of the remaining eight patients, three were known to have chronic chest trouble, two were operated on for empyema, one had a pleurisy, one died in delirium tremens, and one had a pericarditis. Six of the cases that died were in hospital, on an average, only 27 hours.

The subjoined table shows the age-groups of the cases, and the mortality in each group.

Age-group.	Total cases.	Total deaths.	Case-mortality per cent.
7–9	30	0	—
10–19	64	2	3·1
20–29	47	3	6·4
30–39	25	6	24
40–49	34	10	29·4
50–59	17	8	47
60–69	11	4	36·3
70 over	5	4	80
Total	233	37	15·88

These figures may be of value in making comparisons with cases treated with serum.

I am, Sir, yours faithfully,
TOM ANDERSON, M.B., Ch.B.,
Senior Assistant Physician, City of Glasgow Fever Hospital.
Jan. 10th, 1931.

SODIUM AMYTAL IN LABOUR.

To the Editor of THE LANCET.

SIR,—With reference to the two notes which have recently appeared in your columns (Nov. 15th, 1930, p. 1086, Jan. 10th, 1931, p. 92) on the employment of sodium amytal in labour, although I have only used it in eight cases I have come to the conclusion that there are other and better methods of mitigating the pains of labour and I do not propose to test the product further. In one case grs. 9 was given in divided doses of grs. 3 in capsules by the mouth. The patient was noisy, restless, and difficult to control. She had no remembrance of this. Chloroform was administered for the birth of the head. In two cases the second stage was definitely prolonged as a result of the administration of sodium amytal grs. 6 in divided doses at intervals. In another case which received grs. 6, three one day, and three the next at 10.30 A.M., the child was stillborn at 3 P.M. The amytal may have been to blame. Labour was unassisted and natural.

I prefer to use morphine and nitrous oxide gas or rectal avertin. Patients are thankful for avertin which produces amnesia. Except in one case with sodium amytal amnesia was not produced. She was unsatisfactory as described above. The others were quiet but remembered everything, except the final stages for which chloroform was used.

I am, Sir, yours faithfully,
JAMES RIDDELL.
Plymouth, Jan. 10th, 1931.

TREATMENT OF QUINSY BY LAUGHTER.

To the Editor of THE LANCET.

SIR,—Dr. Croft's note in your last issue is interesting in that it gives an actual case of recent occurrence of a phenomenon described in many anecdotes of noted people. Laughing as an accidental cure in quinsy is found mentioned by more than one writer, the most notable instance that occurs to me being the case of Cardinal Mazarin, whose quinsy broke when he laughed heartily at the antics of a monkey seated at the end of his bed. In Webster's "Duchess of Malfi" (iv. 2) occurs the following passage:

> A great physician, when the Pope was sick
> Of a deep melancholy, presented him
> With several sorts of madmen, which wild object
> Being full of change and sport, forced him to laugh,
> And so the imposthume broke.

It is possible that this Pope's case was one of quinsy. I am, Sir, yours faithfully,
MACLEOD YEARSLEY.
Wimpole-street, W., Jan. 11th, 1931.

PASTEURISATION OF MILK.

To the Editor of THE LANCET.

SIR,—It was with real interest that I read Dr. Macfie's letter. My experience has been that many medical men who have not had the time or opportunity to visit Certified or Grade A (tuberculin tested) dairy farms can be divided into two classes: those who think that the whole movement is Utopian, and those who frankly state that they do not believe that, except on occasions, the quality of the work is maintained. In this way in this country the sanatoriums and hospitals have hindered the clean milk movement, but in Scotland a very different story can be told.

While it is true in certain cases that the bacterial standard (involving non-pathogenic organisms) of Grade A (tuberculin tested) milk has not been maintained, it is equally true that failure has been due to lack of efficiency in carrying out the work and not to its impossibility. There can be no question that it is possible to deliver fresh milk from tubercle-free herds of a high standard of bacterial cleanliness, even in the east end of London. Proof of this statement is found in the fact that some 400,000 gallons of such milk were sent to London quite successfully last year. Some of this milk goes to St. Bartholomew's Hospital, which has now been taking it for a number of years, but the greater part is purchased by the poor people living in Bermondsey. I am sure that Dr. D. M. Connan, the M.O.H. of Bermondsey, or Dr.

Ralph Picken, the M.O.H. of Cardiff, will be glad to give Dr. Macfie any information they can of the success or otherwise of the sale of this milk in their districts.

Those who regard pasteurisation as the solution of the whole milk problem must give more consideration than is generally the case to the following points. (1) Evidence is steadily accumulating that our nation is not being nourished as efficiently as we would like. (2) There is a great deal of work which tends to show that the nutritional value of raw milk is greater than that of milk which has been treated. (3) Statistics concerning the incidence of disease must be derived only from the country in which the problem is being considered, since public health conditions in different countries vary very considerably. (4) There is no doubt that a national policy of encouragement for the sale of fresh milk free from disease would be of inestimable benefit to the dairy farmer and veterinary profession. (5) The mere fact that in Berkshire alone there are some 40 or more herds regularly tested with tuberculin is a clear demonstration that the dairy farmer is anxious to do his work to the very best of his ability. It must be remembered that all these farmers have to bear the whole cost of clearing their herds of tuberculous animals, maintaining them clear, and, in addition, have had not only to bear the cost of altering their cowsheds and dairies to enable them to produce clean milk, but also must pay for the privilege of supplying it. They have to create their own market in face of very considerable difficulties, some of which are certainly due to the apathy of the medical profession and the undoubted opposition of some members of the milk industry who prefer to pasteurise or otherwise treat, for the sake of convenience, all their milk-supply.

That pasteurisation offers no encouragement to the producer is clear from a very human remark I once overheard when two licensed producers who did not know me were conversing in an interval of a meeting. The one was dilating on the extreme care he took over every detail on his farm. The other replied, "Yes, I used to do the same, but now I sell to a firm who pasteurises all my milk, so now I need not trouble in the same way."

I am, Sir, yours faithfully,

C. MADDOCK,

Hon. Secretary, The Certified and Grade A (Tuberculin
Tested) Milk Producers' Association.

Foxglade House, Shinfield, Reading, Jan. 12th, 1931.

CLINICAL CONDITIONS ASSOCIATED WITH ACHLORHYDRIA.

To the Editor of THE LANCET.

SIR,—In their interesting paper in your last issue Dr. J. F. Wilkinson and Dr. T. H. Oliver say that I regard achlorhydria as a common factor in the production of cancer of the stomach. I have never made such a statement. On the other hand, if they will read my Schorstein Lecture,[1] they will find abundant evidence that chronic gastritis is a common precursor of cancer of the stomach, and that the achlorhydria found in 60 per cent. of cases of the latter is not secondary to the cancer but is a result of the chronic gastritis which preceded it. This is one reason why I regret that Dr. Wilkinson and Dr. Oliver have not distinguished between achylia gastrica and achlorhydria. Achylia is generally due to an inborn error of secretion and is often familial, but it may also be caused by severe gastritis, which has led to destruction of the oxyntic cells of the stomach. Achlorhydria includes achylia, but also the much larger group of cases in which the absence of free acid is due to chronic gastritis and in which no permanent damage has been done to the mucous membrane.

In achylia gastrica the correct treatment is the administration of 1 to 2 drachms of dilute hydrochloric acid three times a day, but in the achlorhydria secondary to chronic gastritis this treatment is bad, as, though it may relieve the symptoms, it has no effect on the underlying condition, so that recurrence of symptoms occurs directly no more acid is taken, and malignant degeneration of the inflamed gastric mucous membrane may develop at some future period. The correct treatment is to remove the cause, the most common being septic foci in the mouth, throat, or nose, alcoholic excess, and to a less extent indigestible food and insufficient mastication. At the same time the stomach should be washed out every morning with dilute hydrogen peroxide (1 drachm to the pint) till no more mucus is present. This treatment, which results in the restoration of a normal gastric secretion and the cure of the primary gastritis, should always be undertaken when excess of mucus is present in the gastric contents. During the last few years we have found that well over 50 per cent. of cases of achlorhydria are curable in this way, including all our cases of achlorhydria with rheumatoid arthritis and asthma, most of them with gastrogenous diarrhœa and cholecystitis, and even, as you mention in your leading article, two cases of Addison's anæmia.

I am, Sir, yours faithfully,

ARTHUR F. HURST.

Bex, Switzerland, Jan. 11th, 1931.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments have been made: Surg. Comdrs. R. A. Brown to *President* for post-graduate course, and to *Victory*, for Haslar Hospital; W. Bradbury to *Victory*, for Haslar Hospital, for four months' general professional course; and H. R. B. Hull to *Despatch*.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. T. A. Brand to *Vivid*, for R.N. Barracks.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. S. L. Pallant retires on retd. pay.

Maj. J. A. Bennett retires on retd. pay.

Lt. W. A. R. Ross is secd. for duty with the Sudan Def. Force.

TERRITORIAL ARMY.

Lt. W. C. Armstrong to be Capt.

J. D. Pike to be Lt.

ROYAL AIR FORCE.

Flight Lt. J. E. Foran is transferred to the Reserve, Class D.ii.

INDIAN MEDICAL SERVICE.

Lts. B. D. Khurana and J. Singh to be Capts. (prov.) (on prob.).

COMMISSIONS IN THE ROYAL ARMY MEDICAL CORPS.

Twenty-five permanent commission in the R.A.M.C. are being offered to qualified medical practitioners under 28 years of age. Candidates will be required to present themselves in London for interview and medical examination, but there will be no entrance examination. At the same time, a certain number of temporary commissions under similar conditions as regards age and qualifications will also be offered. Applications should reach the Under Secretary of State, the War Office (A.M.D.1), Whitehall, London, S.W., not later than Jan. 19th.

EXTENSION OF WESTMORLAND COUNTY HOSPITAL. A new wing has been added to this institution, which provides 20 additional beds, and flats for the resident medical officer and matron.

---

[1] THE LANCET, 1929, ii., 1023.

OBITUARY

JAMES A. ADAMS, M.D., F.R.F.P.S.G.,

CONSULTING SURGEON TO THE ROYAL INFIRMARY, GLASGOW, AND FORMERLY PRESIDENT OF THE ROYAL FACULTY OF PHYSICIANS AND SURGEONS.

DR. JAMES ADAMS.

IT is always of interest to observe the part played by heredity amongst doctors, and fortunately, in spite of the changes in medical practice, the inclination for the sons of doctors to enter the medical profession seems not to alter. The essentially conservative mind of the professional classes of the North of England, and of Scotland, shows itself in the development of a family-inherited love of the practice of medicine, and the desire to see the sons follow the father's footsteps. Yorkshire boasts with credit of the Teales and the Heys; Lancashire of the Thomas and the Jones families; Scotland of the Monros, and the Marshalls and Cowans. Such "a dynasty of doctors" (as a member of the family called it) exists in the Adams of Glasgow, and the Maxwell-Adams of Lanark, of whom no fewer than 16 members belonged to the profession and could trace their personal and medical ancestry for about 150 years in direct descent.

James A. Adams, who died on Dec. 28th, 1930, at the age of 73, belonged to the Glasgow branch of the family, being the son of the late Dr. James Adams of that city. He was a brilliant student in the University of Glasgow, graduating in 1878 M.B., C.M. with commendation, and in 1881 M.D. with honours. Having surgery as his professional objective he became demonstrator of anatomy under John Cleland, professor of anatomy in the University, and early gave evidence of his keenness of observation and anatomical insight. In 1880 a discussion in the Glasgow Medico-Chirurgical Society on Cerebral Abscess and its Association with Diseases of the Ear was initiated by Dr. Thomas Barr, Glasgow's most distinguished aurist at that time, and apparently the whole subject of the cerebral complications of chronic middle-ear disease was much under discussion. Following upon the discussion Dr. Adams carried out an elaborate investigation on the anatomy of the temporal bone, and published his research in the *Glasgow Medical Journal*, June, 1881, under the title of Certain Anatomical Relations between Abscess of the Brain and Aural Disease. The main argument was to show that there are "anatomical peculiarities of structure in the organ of hearing which differ in the infant and in the adult, which explain the greater frequency of abscess of the brain in adult life as originating from disease of the ear, and that under certain conditions there is an abnormal state of the cerebral circulation which admits of a direct vascular connexion between the ear and the brain." This research paved the way for the brilliant work on Abscess of the Brain which followed a decade later. In March, 1882, in the Medico-Chirurgical Society, he pointed out the anatomical vascular relations of the middle ear and mastoid cells of the brain, and urged the operation of trephining the mastoid process in cases of aural disease where head symptoms appeared even in the slightest degree; and he went further and advocated opening the mastoid antrum in cases of chronic otitis media. His work in the anatomy department led him to suggest the advisability of shortening the round ligaments through incisions over the inguinal canals in the treatment of uterine displacement. This "new operation for uterine displacement," published in the *Glasgow Medical Journal*, June, 1882, soon became known as the Adams-Alexander operation. Adams was very careful to give Dr. William Alexander, of Liverpool, all the credit for priority in publishing successful cases of the operation, though he was correct in pointing out that he had been for 18 months previous to the publication teaching the operation and discussing it with his colleagues. Other papers of this period were on Diaphragmatic Hernia and Voluntary Dislocation of the Hip and Jaw. In 1895 he performed the first successful pylorectomy for malignant disease in Scotland; the case is fully recorded in the *British Medical Journal*, April, 1896; the technique employed was the same as that of Billroth. Dr. Adams showed himself, by these early publications, to be possessed of a considerable degree of originality of anatomical thought in surgery, and his careful practical work in the out-patient department of the Royal Infirmary is well exhibited in a record published in the *Glasgow Medical Journal* of one month's work in the out-patient department, pointing out that the out-patient department was easily the best field for the young surgeon and the student alike. Promotion to full surgeon came to him early in his career, and in 1892 he succeeded Macewen, who was appointed to the chair of surgery in the University. For many years Adams worked in one of the old Lister wards of the Infirmary, and the spirit and tradition of the great master were enthusiastically followed. He was a chief for the long period of 27 years, from 1892 to 1919, carrying on during the war after his term of office had expired. When the Princess Louise Hospital for Limbless Sailors and Soldiers was organised he offered his services as one of the surgeons, and held the post till his retirement.

Dr. Adams was a lover of his profession and ambitious for its honour. He was President of the Royal Faculty of Physicians and Surgeons in 1911, and the Faculty's representative on the General Medical Council from 1920 to 1928, and a sympathetic and knowledgeable administrator of the affairs of the Royal Infirmary. He proved a wise counsellor in medical education.

"Adams," says the writer of a personal appreciation, "was in all respects a notable personality in medical Glasgow. He lived the medical life to its fullest, and found time for its pleasures too. As a raconteur, and a retailer of merry quips and good-tempered raillery, he had no equal. He had many friends, and had the gift of keeping his friendships always in repair. It was a matter of great gratification to him, and is to the profession in Glasgow as well, that the family name and traditional love of the profession of medicine are being carried on so efficiently by his son."

Dr. Adams died at his residence, Balcarnock, Shandon, where he had been living in retirement for the last few years, and the funeral took place at Helensburgh.

M. FITZMAURICE-KELLY, M.B. Lond., F.R.C.S. Eng.

Mr. M. Fitzmaurice-Kelly, who died at Hove, aged 52, on Jan. 5th, had practised surgery at Brighton for ten years, and his judgment and operative skill was much valued by his colleagues. He received his medical education at St. Mary's Hospital, obtaining the senior entrance scholarship in Natural Science in 1897, and qualified M.R.C.S., L.R.C.P. in 1902, being appointed house physician the next year. In 1904 he became successively house surgeon and casualty house surgeon, and in 1905 took the gold medal in the B.S. Lond., and became F.R.C.S. The years 1906 to 1908 Mr. Kelly spent as demonstrator of anatomy in St. Mary's Medical School, being then appointed surgical registrar to the hospital. He had thus acquired considerable surgical experience when he joined the R.A.M.C., within a week of the outbreak of war, as temporary captain, afterwards being promoted to major. He was first attached to a general hospital at Boulogne, and then acted as surgical specialist at Calais, and later for a short time at a casualty clearing station. The severe weather conditions in France in the winter of 1916–17 injured his health; he was invalided home wounded in the summer of 1918, and Armistice Day found him still in hospital. He returned to duty as officer in charge of the surgical wards of the Royal Pavilion Hospital at Brighton, being attached also to the Shepherd's Bush special surgical hospital and to Queen Mary's Auxiliary Hospital, Roehampton. Deciding to settle in Brighton, Mr. Fitzmaurice-Kelly was made surgeon to the Royal Alexandra Hospital for Children and to the Hove General Hospital, and later assistant surgeon to the Royal Sussex County Hospital. He soon acquired and retained till his last illness a prominent position as a surgical consultant in Sussex, and his opinion was greatly valued. While at St. Mary's his main preoccupation was urinary surgery, but his experience at Shepherd's Bush and at Roehampton stimulated his interest in orthopædics, and many of his contributions to the Brighton and Sussex Medico-Chirurgical Society dealt with this branch of surgery. His operation for amputation at the hip-joint was widely known and practised. Mr. Fitzmaurice-Kelly had a fertile and resourceful mind and a strong sense of duty. He was well liked by patients and colleagues, and deep sympathy will be felt for his widow and daughters.

Mr. F. E. Feilden writes: "As a colleague at the Royal Alexandra Hospital for Children, I had ample opportunity of appreciating Fitzmaurice-Kelly's sterling qualities and outstanding personality. He was not a particularly rapid operator, but he was essentially thorough, and spent considerable time in planning an operation and the post-operative treatment. He was a general surgeon of the first order, with a profound knowledge of orthopædic surgery. Probably his most outstanding publication was that dealing with the cure of hernia by means of a living suture, published in 1927. For many years Mr. Fitzmaurice-Kelly was a prominent member of the local branch of the British Medical Association and of the Brighton and Sussex Medico-Chirurgical Society. He had remarkable gifts as a debater, and even those who did not agree with his line of thought admired the clarity with which he presented his case. During the past year Mr. Fitzmaurice-Kelly's health had given his friends considerable anxiety. He faced the gravity of his illness with the same courage and cheerfulness that characterised all his activities."

PANEL AND CONTRACT PRACTICE

Alleged Irregular Prescribing.

AN inquiry committee, consisting of a barrister and two doctors, recently examined certain charges made against a medical practitioner by a borough insurance committee. These charges alleged six different forms of irregularity on the part of the practitioner when prescribing for panel patients, but some of them were later withdrawn. The facts proved or admitted at the inquiry come under three headings:—

(1) On Jan. 27th, 1930, the respondent practitioner sold to a patient a quantity of vaccine ointment for 4*s.* 6*d.*, saying that he did not think it was an ointment which he could obtain for her as an insured person. He then made out a prescription in her name on Form G.P. 26, and in fact obtained a similar quantity of ointment from a chemist. In August, when he knew that complaints were being made against him, he repaid the 4*s.* 6*d.* to the patient and told her that he had obtained the ointment as he did. Explaining this, the respondent said that on Jan. 27th, after the patient left, he thought the matter over and decided to try to get the ointment for her on a prescription. After receiving it he attended her for a confinement, and forgot all about the money. When he remembered it he paid her.—The inquiry committee found that the charge of 4*s.* 6*d.* to an insured person in the circumstances described cannot be justified.

(2) On three dates in March and April the respondent prescribed on Form G.P. 26, 36 cachets for one of his insured patients. He obtained them direct from a chemist, but did not use them in the treatment of this case. Similarly, certain ampoules were prescribed, but not used, for another patient; in this case, however, the patient admitted that she refused to let him give her an injection.—The inquiry committee accepted this explanation.

(3) In seven other cases it was established that the respondent had written prescriptions on Form G.P. 26 and obtained articles himself direct from the chemist. In one case he said he feared to entrust the patient with 100 luminal tablets at once, and therefore gave them in quantities of about ten at a time. He prescribed 100 so as to keep down the cost of prescribing. Most of the other articles were for use by himself for insured persons, and it seemed convenient to obtain them direct.—The committee held that the practice thus described is liable to lead to abuse, "but we were not referred to, and are not aware of, any express prohibition of it in the Medical Benefit Regulations or Terms of Service. . . . There is no evidence to justify us in saying that the respondent adopted the practice of obtaining articles direct from chemists for any ulterior motive."

The inquiry committee recommended that each of the parties should pay their own costs. It stated that the allegations of the borough insurance committee had not been in substance substantiated, and might have been previously investigated by the medical services subcommittee. On the other hand, the respondent's conduct was undoubtedly liable to expose him to suspicion, and he had only himself to blame for being called on to justify or excuse it.

The Minister of Health, having considered the inquiry committee's report, has decided not to remove the respondent practitioner's name from the medical list. He proposes, however, to withhold £5 from the monies payable to the insurance committee in respect of medical benefit, and this will be deducted from the remuneration payable to the practitioner. The Minister makes no order about the costs of the inquiry.

Disciplinary Procedure.

Amendments of disciplinary procedure in national health insurance practice were suggested in a report presented on Tuesday last to a meeting of the Paddington Medical Society. The suggestions are grouped under ten headings:—

(1) All questions involving penalties of any degree should be removed from the punitive jurisdiction of the Ministry of Health and should be judicially determined by a medico-legal tribunal constituted for the purpose and subordinate to the General Medical Council which would have authority to apply suitable penalties.

(2) The proposed area administrative medical officer should advise and assist the clerk to the insurance committee in matters relating to discipline when a practitioner is concerned.

(3) In an appeal to the Minister he may determine the appeal without an oral hearing at his discretion. This should only be allowed when the appeal is based on an alleged irregularity in procedure on the part of any committee having previously dealt with the case.

(4) No distinction should be recognised between private and insured patients in respect of the following voluntary or automatic remedies which should be recognised as adequate for disciplinary purposes for insured and non-insured persons alike:

Change of doctor.
Police and/or county court proceedings.
Action by General Medical Council.

(5) The bulk of increased certification is due as we have shown, to causes beyond medical control. Whilst we consider that "laxity" on the part of a doctor should continue to be amenable to control as at present, any gross carelessness or neglect is accurately described as "false certification" and should for disciplinary purposes come logically under the control of the General Medical Council. At first sight it appears that the insurance practitioner enjoys a privileged position in respect of control by insurance and panel committee of his certification. This is not so inasmuch as their control is *additional* to that of the General Medical Council.

We suggest that one respect in which the General Medical Council could be reorganised is that such disciplinary control of insurance certification as appears necessary should be administered by a body definitely subordinate to the General Medical Council. Advantages following would be:—

(*a*) Uniformity in the definition of "laxity" and a clearer distinction between this and the factors in the increase of certification over which the practitioner has no control.

(*b*) The removal from medical administration in the Ministry of Health and in the local committees of the judicial and punitive elements which properly belong to the law courts, the General Medical Council, or elsewhere.

(6) The application of a suitable surcharge to patient, as recommended in respect of certain medicines, &c., prescribed, would deal with the bulk of the existing difficulties in connexion with prescribing. Inefficient prescribing should primarily be inquired into as at present. But the institution and application of penalties should again be in the hands of a suitable medico-legal tribunal constituted ad hoc by the General Medical Council.

(7) As these changes in any case would take a certain amount of time to affect we suggest, as an immediate measure, that all decisions adverse to a practitioner should be subject to appeal to a higher court.

(8) These recommendations are made with special regard to the situation which is likely to arise if and when extensions of the Acts ensue.

(9) Administrative control and regulation, of course, should remain as at present under the jurisdiction of the Minister except that penalties or dismissal would thus depend on the discretion of a professional disciplinary tribunal external to the Ministry of Health.

(10) We recognise that these recommendations depend not only on a considered extension of the present functions of the General Medical Council but also, on an alteration of the present constitution of the Council such as would give the insurance practitioner, as such, a more equitable representation thereon.

MEDICAL NEWS

University of Cambridge.

Diploma in Medical Radiology and Electrology.—The following recommendation from the Faculty Board of Medicine was passed by the Senate on Dec. 10th, 1930: "The Faculty Board have had under consideration the annual report of the committee for medical radiology and electrology, as well as other information relating to the Diploma. The Board are convinced by the evidence laid before them that the Diploma continues to meet a real need, and that the standard of the teaching and of the examination is satisfactory. The financial position also is satisfactory. The Board therefore are of opinion that the Diploma should be re-established for a period of three years, but that, in view of the rapid growth in allied subjects, the position and scope of the Diploma and the arrangements made with the British Institute of Radiology should be reviewed before the expiration of that period."

Royal College of Surgeons of England.

A meeting of the Council was held on Jan. 8th, with Lord Moynihan, the President, in the Chair.

Mr. Russell J. Howard, Mr. E. C. Hughes, and Mr. L. E. C. Norbury were admitted Members of the Court of Examiners. —Mr. Wilfred Trotter was appointed Hunterian Orator for 1932 and Mr. W. Sampson Handley Bradshaw Lecturer for 1931.—Mr. J. H. Thompson, of King's College, was appointed Melchett research scholar, the subject of his research to be Investigation into the Influence of the Parathyroid Gland on Processes of Growth.—The Hallett Prize was awarded to Mr. J. C. R. Hindenbach, of the University of Otago, on the result of the recent examination in anatomy and physiology for the Fellowship.

Diplomas of Membership were granted to S. S. Ahluwalia (Punjab and Univ. Coll.), W. N. Chalmers (Liverpool), and E. M. Sharples (St. Bartholomew's). Diplomas in psychological medicine and laryngology were granted jointly with the Royal College of Physicians.

It was reported that the Primary Examinations for the Fellowship to be held in the Dominions in 1931 would begin on August 11th at Melbourne and on Oct. 20th at Toronto.

The Council adopted the following answer to the resolution passed at the annual meeting of Fellows and Members on Nov. 20th last: "The main functions of the College are to promote and encourage the art and science of surgery for the common weal, and for this purpose to conduct the examinations of the College and to maintain the great Museum and Library placed under its care. In carrying out these functions the Council organises lectures and demonstrations, provides facilities for and encourages research, fosters social intercourse and the amenities of the profession, and in every way possible renders the College an instrument for the advancement of surgery in its widest sense, not only for the benefit of the Members and Fellows, but the whole profession throughout the Empire. In the opinion of the Council these functions are well carried out under the present constitution; after further and prolonged deliberation the Council has therefore decided that it is not desirable to alter the constitution of the College by providing for the direct and separate representation of Members of the College upon the Council. The decision of the Council is in conformity with the opinion expressed three years ago by the body of Fellows of the College who are the electorate."

University of Liverpool.

At recent examinations the following candidates were successful:—

D.P.H.

E. Hughes and J. W. Pickup.

University of Glasgow.

Dr. John Shaw Dunn has been appointed to the St. Mungo (Notman) chair of pathology in succession to the late Dr. J. H. Teacher. Prof. Dunn is at present professor of pathology in the University of Manchester.

Royal Sanitary Institute.

On Tuesday, Feb. 10th, at 6 P.M., at 90, Buckingham Palace-road, London, S.W., Lieut.-Colonel William Butler, Senior Medical Officer, London County Council, will open a discussion on Recent Methods of Sewage Treatment.

The Huxley Lecture.

The staff of Charing Cross Hospital and Medical School has invited Prof. Sigmund Freud to deliver the next biennial Huxley Lecture at the Medical School. Previous lecturers include Lister, Virchow, Pavlov, Flexner, and Gowland Hopkins.

The National Diet.

Prof. E. P. Cathcart will deliver two lectures, under the auspices of the University of London, on Feb. 23rd and 24th, on the National Diet. The lectures will be given at the London School of Hygiene and Tropical Medicine, Gower-street, at 6 P.M. on each date, and the chair will be taken by Sir Walter Fletcher on one day and by a member of the Board of Management of the School on the other. Admission is free.

Harveian Society of London.

This society is embarking on its centenary year, having been founded in 1831. At the annual general meeting on Jan. 8th the following officers were appointed:—President: Sir Thomas Horder. Vice-Presidents: Dr. Montague Smith, Dr. K. Playfair, Dr. H. C. H. Bull, and Dr. G. E. Oates. Hon. Secretaries: Mr. Cecil P. G. Wakeley and Dr. R. Cove-Smith. Treasurer: Dr. G. de B. Turtle. Council: Dr. A. C. Alport, Dr. W. F. Christie, Dr. Macdonald Critchley, Dr. A. H. Douthwaite, Mr. H. C. Edwards, Mr. D. C. L. Fitzwilliam, Dr. E. L. Gowlland, Prof. Tom Hare, Dr. T. C. Hunt, Dr. G. E. Orme, Mr. H. Rivers Pollock, and Mr. H. L. C. Wood.

Lister Institute of Preventive Medicine.

On the occasion of the recent retirement of Sir Charles Martin and Prof. Arthur Harden from the staff of the Institute, many of their colleagues and other research workers, past and present, met in the library of the Institute to offer parting gifts to their two distinguished colleagues. Prof. J. C. G. Ledingham, who is succeeding Sir Charles Martin as Director, presided over the meeting, and referred to the fact that only a few years ago a very similar gathering had assembled to express the great satisfaction which the conferment of knighthood on their Director had given them, and to celebrate the occasion by presenting him with his portrait. The staff of the Institute, he said, was losing the splendid services of both their friends because they had reached the prescribed age-limit, but they had completed their terms while still in their full mental vigour. Sir Charles had directed successfully the activities of the Institute for 27 years, the success of his administration being due to his tact, his business ability, and the catholicity of his scientific interests. Prof. Harden had served the Institute for 33 years and as Biochemist-in-Chief during that period had made his department an important centre of biochemical research. Only a year ago he had been awarded a Nobel prize in Chemistry for his work on fermentation. It was undoubted that the departure of Sir Charles Martin and Prof. Harden would mean a severe loss to the Institute's forces, but it was to be hoped that the traditions they had set would long remain a potent source of inspiration to their successors. On behalf of the many subscribers at home and abroad Miss Harriette Chick was called upon to present to Sir Charles and Lady Martin a silver coffee service designed and executed by Mr. P. S. Alexander, of Walberswick, Suffolk. Miss Muriel Robertson then unveiled and presented to Prof. Harden his portrait in oils by Mr. Neville Lewis. Sir Charles Martin and Prof. Harden, in returning thanks for these gifts, referred in reminiscent terms to the developments they had witnessed in the scope of the Institute's activities during their long service, and at the close of the reception which concluded the ceremony, they took leave of their colleagues.

Sir Charles and Lady Martin sailed on Jan. 2nd for Cape Town en route to Australia, where, as announced already in our columns, Sir Charles is taking up the position of Director of the Division of Animal Nutrition under the Commonwealth Council for Scientific and Industrial Research.

Medical Society of Individual Psychology.

Members of the medical profession are invited to hear Dr. Alfred Adler address this society at 11, Chandos-street, W., at 8.30 P.M. to-day, Friday, Jan. 16th. His subject is the Structure of Neuroses.

Post-graduate Course in Tuberculosis.

Under the auspices of the Joint Tuberculosis Council a post-graduate course will be held at the City of London Hospital for Diseases of the Heart and Lungs and elsewhere from Feb. 16th to 21st. Particulars may be had from Dr. William Brand, 8, Highway-court, Beaconsfield, Bucks.

British Empire Cancer Campaign.

Sir Charles Gordon-Watson presided at a meeting of the Grand Council on Jan. 12th. A grant of £6000 was made to the Middlesex Hospital towards cancer research in the year 1930–31, and a further grant of £600 making a total of £3600 since 1925, was authorised to the cancer research committee of the Marie Curie Hospital for the services of its medical research officer.—Sir Cuthbert Wallace, Director of the Radium Institute, London, was elected a member of the Grand Council and Prof. F. T. G. Hobday, Principal of the Royal Veterinary College, was also invited to become a member.—The Council approved the arrangements in connexion with the Garton prize of £500 and gold medal which is to be awarded to the person, or persons, submitting the best original dissertation on The Early Diagnosis of Cancer by December, 1931. It was announced that the Biological Effects and Mode of Action of Radiations upon Malignant and other Cells will be the subject for the second Garton Prize and Medal, the dissertations for which must be received by December, 1933.

It was reported that the popular handbook entitled "The Truth about Cancer" issued to the public on Dec. 4th, was now obtainable from all booksellers or direct from the publishers, Messrs. John Murray, at 2*s.* 6*d.* per copy. The book had been received with appreciation in all directions, and later editions would be issued so that it would keep abreast of developments.

Donations and Bequests.

Among other bequests the late Mr. John Bromilow Holt, of Heywood, Lancs, left £1000 each to the Manchester Royal Infirmary, the Bury Infirmary, St. Dunstan's Hostel for Blinded Sailors and Soldiers, and the National Society for the Prevention of Cruelty to Children; £750 each to the Royal Society for the Prevention of Cruelty to Animals, Dr. Barnardo's Homes, and Lord Mayor Treloar's Cripples Hospital; and £250 to the Heywood Crippled Children's and Holiday Home, Congleton.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Jan. 20th.—5.30 P.M., GENERAL MEETING OF FELLOWS. 8 P.M., PATHOLOGY.

WEDNESDAY.—8.30 P.M., Fellows and their friends will be received in the Library by the President and Mrs. Watts Eden. At 9.15 P.M. Dr. Arnold Chaplin will give an address entitled Great Figures in History, or Misconceptions Removed. Various objects of interest will be exhibited in the Library.

THURSDAY.—8.30 P.M., UROLOGY. Paper: Dr. S. Gilbert Scott: The Significance of the Radiological Renal Outline.

FRIDAY.—5 P.M., DISEASE IN CHILDREN. (Cases at 4.30 P.M.). 8 P.M., EPIDEMIOLOGY. Paper: Prof. E. L. Collis: Recent Views on Pneumonoconiosis.

HUNTERIAN SOCIETY.

MONDAY, Jan. 19th.—9 P.M. (at Apothecaries' Hall, Water-lane, E.C.), Dr. Arnold Lorand (Carlsbad): Problem of Rejuvenation.

MEDICO-LEGAL SOCIETY.

Thursday, Jan. 22nd.—8.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Dr. Nathan Raw: The Coroner's Verdict in Cases of Suicide, to be followed by a discussion.

LONDON CLINICAL SOCIETY.

TUESDAY, Jan. 20th.—9 P.M. (at The London Temperance Hospital), Dr. Geoffrey Evans will open a discussion on the Importance of Diet in Health and Disease.

CHELSEA CLINICAL SOCIETY.

TUESDAY, Jan. 20th.—8.30 P.M. (at the Hotel Rembrandt, Thurloe-place, S.W., preceded by dinner at 7.30 P.M.). Discussion on the Treatment of Eczema. (Opener: Dr. Henry MacCormac.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.

MONDAY, Jan. 19th.—5 P.M., Mr. Victor Bonney: Results and Technique of Myomectomy.

WEDNESDAY.—5 P.M., Mr. Basil Hume: Pathology of Diaphragmatic Hernia.

FRIDAY.—5 P.M., Mr. Tudor Thomas: Grafting of the Cornea in Rabbits.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 19th, to SATURDAY, Jan. 24th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Mon., at 4 P.M., free lecture by Mr. V. Zachary Cope on the Acute Abdomen. (Early Diagnosis Series.) —METROPOLITAN HOSPITAL, Kingsland-road, E. Mon., at 2 P.M., free post-graduate demonstration in Out-patient Department by Dr. N. H. Hill.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Tues., at 2.30 P.M., free post-graduate demonstration on Injection Treatment of Hæmorrhoids by Mr. Rodney Maingot.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Jan. 19th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (Public Health Division), Keppel-street, Gower-street, W.C.

MONDAY, Jan. 19th.—3 P.M., Mr. D. S. Rabagliati: Veterinary Science in Relation to Public Health.

WEDNESDAY.—3 P.M., Prof. J. W. H. Eyre: Shell-fish and the Public Health. 4 P.M., Mr. F. C. Minett: Certain Diseases Common to Man and the Lower Animals.

UNIVERSITY OF LONDON, University College, Gower-street, W.C.

TUESDAY, Jan. 20th.—3.30 P.M., Mr. Pryns Hopkins: The Need of Psychologists and the Menace from Charlatans. (First of a course.)

UNIVERSITY COLLEGE MEDICAL SCHOOL, University-street, W.C.

TUESDAY, Jan. 20th.—5.15 P.M., Dr. J. A. Murray: Induction of Cancer by Tar and other Agents.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Jan. 22nd.—9 P.M., Sir Charlton Briscoe: Postural Pulmonary Complications.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.

THURSDAY, Jan. 22nd.—5 P.M., Mr. W. M. McCullagh: Treatment of Post-partum Hæmorrhage.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Jan. 23rd.—4 P.M., Mr. Archer Ryland: Demonstrations of Museum Specimens.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 20th.—3.15 P.M., Mr. F. D. Saner: Selected Cases.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Jan. 20th.—5 P.M., Dr. J. A. Drake: Urticaria.

THURSDAY.—5 P.M., Dr. W. J. O'Donovan: Exfoliative Dermatitis.

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.

THURSDAY, Jan. 22nd.—3 P.M., Dr Wilfred Harris: Clinical Demonstration.

Appointments

CULLEN, C. K., L.R.C.P. Lond., M.R.C.S., D.P.H., has been appointed Tuberculosis Officer, Shoreditch.

DAVIES, D. B., M.B. Ch.B. Edin., Medical Officer for Pontlottyn, Glam.

MOIR, J. H., M.D., Ch.B. Aberd., D.P.H., to be Certifying Surgeon under the Factory and Workshop Acts for Church Gresley, Derby.

ROBERTS, J. T. C., M.B., Ch.B. Liverp., D.P.H., Medical Officer of Health, Dukinfield and Hollingworth.

RUSHWORTH, J. A., L.R.C.P. Lond., M.R.C.S., Assistant to Medical Superintendent, Liverpool Sanatorium.

WYNN-WILLIAMS, N. R., M.B., B.S. Lond., Resident Assistant Physician to Montana Hall, Montana, Switzerland.

Gloucester County and City Mental Hospitals: KNIGHT, C. V., M.D. Lond., L.R.C.P. Lond., M.R.C.S., Consulting Surgeon; TERRY, H. CAIRNS, M.B., Ch.B. Birm., Consulting Physician; NICCOL, W., M.B., Ch.B. Glasg., Consulting Oculist; BERNSTEIN, S., L.R.C.P. Lond., M.R.C.S., Consulting Ear, Throat, and Nose Surgeon; GOSS, J., M.B., B.Chir. Camb., Consulting Radiologist; and DAVEY, E. N., M.B., B.Ch. N.U.I., Consulting Pathologist.

Vacancies

For further information refer to the advertisement columns.

Altrincham General Hospital.—Sen. and Jun. H.S.'s. At rate of £150 and £120 respectively.

Ascot, Heatherwood Hospital.—Res. Asst. M.O. £300.

Bedford, Bedfordshire Sanatorium.—Res. Asst. M.O. £400.

Birmingham, Dudley Road, Hospital.—Jun. Asst. M.O.'s. Each at rate of £200.

Birmingham General Hospital.—Res. Anæsthetist. £120. Also Res. H.P. and H.S. Each £70.

Bolton Infirmary and Dispensary.—Cas. O. At rate of £150.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150.

Bradford Royal Infirmary.—Two H.S.'s. Each at rate of £150.

Brighton, Royal Sussex County Hospital.—Hon. Asst. Surgeon.

Brighton, Steyning Institution.—Res. M.O. and Asst. Administrative County M.O. £600.

Bristol Royal Infirmary.—H.P.'s and H.S.'s to Special Depts. All at rate of £60.

Bury St. Edmunds, West Suffolk General Hospital.—Res. H.P. and Obstet. O. £150.

Cambridge, Papworth Village Settlement.—2nd and 3rd Asst. M.O.'s. At rate of £400 and £200 respectively.

Charing Cross Hospital, W.C.—Asst. Obstetric Physician.

Chelsea Hospital for Women, Arthur-street, S.W.—Registrar. £50.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Dudley, Guest Hospital.—Asst. H.S. £160.

Durham, Seaham Hall Sanatorium.—Med. Supt. £600.

East London Hospital for Children, Shadwell, E.—H.S. At rate of £125.

Epsom, Surrey, Horton Mental Hospital.—4th Asst. M.O. £575

Evelina Hospital for Children, Southwark, S.E.—Hon. Dental Surgeon. H.P., Cas. and Out-patient Officer. Also H.S. All at rate of £120.

Golden-square Throat, Nose, and Ear Hospital, W.—Hon. Anæsthetist.

Hertford County Hospital.—H.P. £150.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—H.P. At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Surg. Reg. £300. Also Refraction Asst. for Ophthalmic Dept. 1 gn. each attendance.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—Asst. Radiologist.

Ilford, King George Hospital.—Hon. Gynæcological Surgeon. Also H.S. At rate of £100.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Leicester, City Isolation Hospital and Sanatorium, Groby-road.—Jun. Asst. M.O. £300.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool County Borough Local Educational Authority.—Jun. Asst. School M.O.'s. Each £500.

Liverpool Eye and Ear Infirmary, Myrtle-street.—H.S. £100.

Liverpool, St. Paul's Hospital, Old Hall-street.—H.S. At rate of £120.

London Homœopathic Hospital, Gt. Ormond-street and Queen-square, Bloomsbury, W.C.—Three Res. M.O.'s. Each £100.

Manchester Royal Infirmary.—Jun. H.S. and Cas. O. for Central Branch, Roby-street. £100–£200.

Manchester, St. Mary's Hospitals.—Sen. Asst. M.O. for Children's Out-Patient Dept. Also Jun. Asst. M.O. At rate of £100 and £50 respectively.

Margate Royal Sea Bathing Hospital, &c.—H.S. At rate of £200.

Middlesbrough Education Committee.—Sen. Asst. School M.O. £500.

Northampton General Hospital.—Hon. Asst. Physician.

Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.

Plymouth, Central Hospital.—H.S. £130.

Poole, Dorset, Cornelia and East Dorset Hospital.—H.S. At rate of £150.

Rochdale Infirmary and Dispensary.—Jun. H.S. £200.

Royal London Ophthalmic Hospital, City-road, E.C.—Out-Patient Officer. £100.

St. George's Hospital, S.W.—Asst. Ophth. Surgeon.

St. Mark's Hospital for Cancer, City-road, E.C.—Res. Surg. O. £150.

St. Mark's Hospital for Fistula, Cancer &c., City-road, E.C.—Two Anæsthetists. Each £25.

Sheffield, Royal Hospital.—Ophth. H.S. £120. Also Res. Anæsthetist. £80–£100.

Sheffield Royal Infirmary.—Asst. Aural and Ophth. H.S. At rate of £80.

South Shields, Harton Hospital.—Two H.S.'s. Each £150.

Wallasey, Victoria Central Hospital.—Jun. H.S. At rate of £100.

Wigan, Royal Infirmary.—Third H.S. At rate of £150.

Willesden General Hospital, N.W.—Registrars.

Worcester, County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Breage (Cornwall); Knighton (Radnor); Llangennech (Carmarthenshire); Sudbury (Suffolk); and at Tewkesbury (Glos.).

The Home Secretary is considering the question of appointing an additional Medical Referee under the Workmen's Compensation Act for the Falkirk district of the Sheriffdom of Stirling, Dumbarton, and Clackmannan. Applications should reach the Private Secretary, Scottish Office, Whitehall, London, S.W.1, not later than Feb. 3rd.

PAULTON ISOLATION HOSPITAL.—Last week Mr. F. Gould, M.P. opened a Joint Isolation Hospital at Paulton, Somerset. The hospital, which has cost £13,400, will serve the needs of several rural and urban districts.

NOTES, COMMENTS, AND ABSTRACTS

TROPICAL DISEASE IN LIBERIA.

LIBERIA, a rich country, constitutes at present the one totally unexplored stretch of West Africa. This Negro Republic was founded as an American Colony about 110 years ago, and since the Treaty of Versailles the United States has been acting as its adviser in Liberian affairs. A report of the Commission appointed to inquire into the existence of slavery in the native West African Republic has just appeared, and exposes a condition of misgovernment which it is certain will not be allowed to continue now that public attention has been called to the horrible facts. The abuses whose existence is thus revealed have been suspected for a long time, and have been hinted at by at least one well-known writer, but as a matter of fact very little is known about the interior of Liberia, and Americo-Liberians, who form the ruling section of the Republic, would appear to be unable to penetrate further than 30 miles from the coast under some legal restrictions.

Some of this unfortunate ignorance will be dissipated by the generosity of the department of Tropical Medicine and Institute of Tropical Biology of Harvard University, for there has now appeared issued by that Department a magnificent account of an expedition working in 1926–27 in the African Republic and inquiring into the incidence of tropical disease. The members of the expedition were Prof. Richard P. Strong, Professor of Tropical Medicine in the Harvard Medical School, and Drs. Glover M. Allen, Joseph C. Bequaert, Harold J. Coolidge, David H. Linder, George C. Shattuck, Max Theiler, and Loring Whitman. Their observations and notes on the material collected have been ably edited by Prof. Strong.[1]

Many are familiar with the work of the Department of Tropical Medicine of Harvard University, and with the results of former expeditions to South America under the leadership of Prof. Strong, so that the appearance of these two particularly fine octavo volumes, dealing with analogous activity in Liberia, will be welcomed with appreciation. The two volumes, totalling 1052 pages, are replete with close print and furnished with nine maps and 476 photographic figures, of which 15 are in colour; there are also 28 text-figures presented for study. It is particularly appropriate that the work should be dedicated to Harvey S. Firestone as the man who has done so much for the development of the country and for the welfare of its inhabitants. Mr. Firestone has acquired a 99 years lease of a million acres of land upon which to develop the growth of rubber, and it is unthinkable that such operations should proceed without due attention to the findings of the recent Commission.

ROUTE, CLIMATE AND CONDITIONS.

The observations here recorded were made both along the sea-coast and in the interior. The country was crossed in three directions and investigations were carried out on the way from base camps established at strategic points. No trustworthy maps of the hinterland of Liberia were in existence. The greater part of the country has not been accurately surveyed from a geographical standpoint, and the maps already published are grossly inadequate and inaccurate. Consequently the maps in this report, compiled mainly by the energy of the Firestone Company and that of the expedition, may be taken as authoritative of the country at present. Investigations in Liberia being completed, the route travelled by the expedition across Africa was through the Belgian Congo, following the course of the Congo River and the Lualaba to Kabalo. From Kabalo the expedition proceeded by rail to Albertville on Lake Tanganyika and thence travelled north-east to Kigoma, Lakes Kivu and Edward, the Semliki Valley, Kivu and the Ituri forest. In all some 1500 miles were done on foot along trails and incompleted roads. Finally the party reached Entebbe on Lake Victoria.

The climate on the Liberian Coast is insalubrious, mainly due to the combination of excessive humidity with continuous, but not excessive, heat. At nine o'clock in the morning it is unpleasant to walk, one perspires throughout the day, even in the house. The towns on the coast have an average temperature of 76° F. to 80° F. and a seasonal variation of a very few degrees, making them unpleasant places of residence for unseasoned visitors, but the interior of the country is more salubrious. The conditions in the forests of Liberia have remained practically unchanged during the last fifty years since Stanley first opened up Central Africa to the white man, so that the success of this expedition of eight Americans, who spent almost a year in tropical Africa, in remaining free from tropical disease, once more demonstrates that in any parts of the dark continent white man can travel and not succumb to disease, provided that necessary hygienic precautions are taken. Much thought and continued care were necessary in exercising the proper precautions. The prophylactic use of quinine was considered necessary. True, it has been amply demonstrated that malaria infection cannot be prevented, even if as much as 1 gramme of quinine is taken daily, yet the members of the expedition are convinced that it masks a number of infections, eliminates some, and definitely modifies the virulence of others. In short, it materially influenced the efficiency of the expedition by its influence upon malaria.

THE TROPICAL SCOURGES.

The first volume deals with the diseases chiefly encountered in Liberia—malaria, blackwater fever, filariasis, onchocerciasis, juxta-articular nodules, schistosomiasis, leprosy, yaws, syphilis, granulomatous and parasitic conditions of the skin, ainhum, intestinal parasitism, amœbic dysentery, tuberculosis and diseases of the genital organs, notably gonorrhœa. Bacillary dysentery, typhoid fever, trypanosomiasis, yellow fever, and nutritional disturbances are rarer, whilst bubonic plague and relapsing fever are seldom found.

With particular regard to malaria, Dr. Shattuck concluded from his clinical studies that splenic enlargement does not seem to be a reliable indication of the disease in Liberia. Non-enlargement of the spleen does not exclude malaria, while splenomegaly is not uncommon in association with a negative blood examination. In only 4·7 per cent. was it definitely enlarged, which is a particularly low rate as compared to what prevails in Amazonia. In one case the diagnosis was lymphatic leukæmia, in a second schistosomiasis. The existence of a separate disease *Splenomegalia mycotica* is discussed, but considered problematical. No cases of yellow fever occurred whilst the expedition was in the country, although six had been reported shortly before their arrival. Schistosomiasis does not appear to be uncommon in Liberia and the eggs of *S. hæmatobium* were found in the urine in one case, and the lateral-spined *S. mansoni* in the fæces. In one instance the eggs of *S. hæmatobium* were present in fæces and those of *S. mansoni* in urine. Filariasis is prevalent both upon the coast and in the interior. At Gbanga in a series of 105 natives examined, *Filaria bancrofti* was found in two instances, *A. perstans* in one, and *Loa loa* in one.

Culicoides grahami, one of the insect vectors of *A. perstans*, was found inland and in the Belgian

Congo. It was not, however, very abundant during the time the expedition was in the country. Elephantiasis, particularly of the lower extremities and scrotum, was found to be common, more especially amongst the adult Krus. Verrucose papillomatosis of the skin presented such a striking appearance that it might be confused with "mossy foot"! In a cystic tumour of the forearm removed by Dr. C. C. Chesterman on the Upper Congo, an adult *Loa loa*, 5 cm. in length, lying free in the fluid was demonstrated. Curious to relate the guinea-worm is not common. Infection with *Onchocerca volvulus* was first observed in the interior at an altitude of 900 ft. In the same region numbers of *Simulium damnosum* occurred and in dissections of adult flies caught near a village, developmental forms of onchocerca were successfully demonstrated. Histological studies of onchocerca tumours revealed spindle-shaped cells suggestive of fibrosarcoma. It was further observed that African subjects of these tumours are very liable to keloid formations, of which some remarkable illustrations are given.

The ætiology of that curious condition known as juxta-articular nodules, which appears to be fairly common, was carefully studied and a minute investigation of the cellular pathology made. It seemed probable that these growths originated from some form of mechanical irritation, just as other true neoplasms may, and that in some instances they were onchocercal in origin, in others frambœsial or syphilitic. It is pointed out, however, that the disease is rare in white people, in whom only 25 cases have been reported, while a few have been found in individuals who have never been outside Europe. Syphilis and yaws, grouped under the convenient generalisation—treponemiasis—claimed a great deal of attention. Regarding the vexed question of their identity, the observers have been unable to add any considerable additional knowledge. They consider themselves justified in regarding yaws as an attenuated virus of syphilis, less virulent in producing a disease modified by the portal of entry through many years of successive passage via the epidermis of black skinned races, and by the habits of these people plus the climatic and hygienic conditions under which they live. Other chapters deal with the terrible disfiguration known as gangosa and rhinopharyngitis mutilans—possibly also spirochætal infections. Goundou was seen in children in whom it formed striking paranasal lesions and leprosy occurred associated with dermal moniliasis. One case of sporotrichosis was discovered and the blastomycotic elements demonstrated in sections of the skin. Other fungous invasions of the epidermis were studied in the same manner and are well illustrated by sections removed at biopsy. Under other pathological conditions are grouped neoplasms, tuberculosis, and trypanosomiasis, the latter being very rare in Liberia was studied on the upper reaches of the Congo.

A chapter is devoted to plant parasitic diseases, another, and a very considerable one, to similar infections of wild animals, mainly game shot in Congo Ituri District. In a section on some parasitic helminths collected by the expedition, J. H. Sandground has made a very considerable contribution to animal helminthology, while in addition a new species *Tylenchus alatus* is described from the root of young cinchona plants. Special protozoological studies of the blood with two finely coloured plates are from the pen of Max Theiler. The botanical report by D. H. Linder is sound and informing.

The second volume consists entirely of pure zoology and is a record of the mammals, birds, reptiles, and amphibians collected in Liberia and on the Congo, while it is hardly surprising to note that the very complete account of entomology occupies more than half the volume.

There is no doubt that the labours of this Harvard Expedition will re-echo in many other departments of science and will form a record which will be consulted by specialists for many years to come.

NEW PREPARATIONS.

SEDICYL (from the Dr. Joachim Wiernik and Co. Chemical Works in Berlin. Agents, Coates and Cooper, 41, Great Tower-street, London).—We have received a specimen of this choline derivative which has recently been used in Germany in gynæcology, previous experimental work on rats having shown that the substance influences the correlation disturbances of the climacterium, and exerts a physiological action on the nervous system, as evidenced by its value in face of such symptoms as giddiness, headache, and palpitation. The manufacturers state that it is absolutely harmless, and can be used for prolonged treatments without any undesirable after-effects. It is put up in tubes of 25 tablets each, and the dosage is one or two tablets three times daily with a subsequent reduction to two tablets per day, when the substance will still exert its effect.

DIMOL PESSARIES (Dimol Laboratories, Ltd., 40 Ludgate-hill, London; Distributing Agents, Messrs Sangers, 258, Euston-road, London) is a new Dimo preparation, the *gelatin* pessaries being guarantee to contain individually the equivalent in bactericida action to half a drachm of pure carbolic acid, whil the claim that they are free from any untowar action on the mucosa is a recommendation to the use in midwifery and gynæcology. The pessaries ar put up in cartons containin one dozen in each.

EPHEDRINE Nasal Jelly, Inhalant Compoun and Throat Spray.—We have received from Britis Drug Houses, Ltd., Graham-street, City-road, Londo samples of these three forms of B.D.H. ephedrin the alkaloid from the Chinese plant, Ma Huan being made by a special process to which the fir attach particular importance. The nasal jelly, whic is put up in collapsible tubes, is composed of ephedri in pure soft petroleum; the inhalant is a solution the drug in liquid paraffin with menthol, campho and oil of thyme; and the throat spray is an aqueo solution of the hydrochloride of ephedrine wi chlorbutal. Ephedrine is, of course, similar in actio to adrenalin, the circulatory stimulation being marke The different salts have proved useful in the treatme of certain types of asthma, in hay-fever, and co gestion of the nasal mucous membrane.

Births, Marriages, and Deaths

MARRIAGES.

MAY—KAYE.—On Jan. 3rd, at Holy Trinity Church, Brompto road, Richard W. L. May, M.A., M.B., B.Ch., of Eto Windsor, to Winifred, only child of Mr. and Mrs. Kaye, Hatfield, Hendon-lane, N.

THOMAS—THOMAS.—On Jan. 6th, at the Parish Church, Ris William Evans Thomas, M.D., J.P., of Llys-y-graig, Ystr to Catherine Elizabeth, widow of D. J. Thomas, M.R.C. J.P., of The Rhyl, Porthcawl.

WAY—SCOTT FOSTER.—On Jan. 9th, Montague Way, J. M.R.C.S., L.R.C.P., to Margaret, youngest daugher of t late Sir Scott Foster, J.P.

DEATHS.

ABBOTT.—On Jan. 11th, at Lake House, Wrightington, Lan after a long illness, Dr. Frederic William Abbott, former of Balham and Christchurch, in his 68th year.

CLARK.—On Jan. 7th, at his residence, Great George's-roa Waterloo, near Liverpool, John Barclay Clark, M.D., C. Edin., aged 90 years.

MANSEL.—On Jan. 8th, at Brentwood, Essex, Charles Jo Linskill Mansel, O.B.E., M.D.

O'HERLIHY.—On Jan. 9th, at Monte Carlo, Dr. Corneli O'Herlihy, of Inniscarra, Co. Cork, aged 47.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices Births, Marriages, and Deaths.

INDEX TO "THE LANCET," VOL. II., 1930.

THE Index and Title-page to Vol. II., 1930, whic was completed with the issue of Dec. 27th, is now i preparation. A copy will be sent gratis to su scribers on receipt of a post-card addressed to th Manager of THE LANCET, 7, Adam-street, Adelph W.C.2. Subscribers who have not already indicate their desire to receive Indexes regularly as publishe should do so now.

ADDRESSES AND ORIGINAL ARTICLES

THE TECHNIQUE AND RESULTS OF MYOMECTOMY.*

By Victor Bonney, M.S., M.D., B.Sc. Lond.,
F.R.C.S Eng., F.C.S.A.,
GYNÆCOLOGICAL SURGEON TO THE MIDDLESEX HOSPITAL; SURGEON TO CHELSEA HOSPITAL FOR WOMEN.

In the dawn of abdominal surgery, when Spencer Wells and other pioneers were proving the practicability of intraperitoneal operations, it occasionally happened that a tumour, supposed to be an ovarian cyst, turned out to be a fibroid attached to the uterus by a stalk and hence capable of being removed by the technique employed in ovariotomy. Myomectomy is therefore one of the oldest of the abdominal operations, but its development has been very slow. For many years after ovariotomy had obtained full acceptance the uterus remained a territory almost forbidden to the abdominal surgeon except for the occasional and mostly accidental removal of pedunculated fibroids. That myomata could be enucleated became apparent as surgery, increasingly daring, began to deal with tumours having shorter and shorter pedicles, until at last it essayed to cope with those having none at all. A new problem immediately presented itself, for the technique of ovariotomy was not applicable to a tumour that was sessile or embedded. The difficulty was twofold: how to control the bleeding caused by the enucleation, and how to close the cavity left by the tumour. Instead of solving the problem, surgery circumvented it by making the lower segment of the uterus itself the pedicle of the tumour and applying to it the technical management of a cyst pedicle.

From that time onwards the method of performance of abdominal hysterectomy was steadily improved upon by successive generations of gynæcological surgeons until since a number of years now a technique has been established impossible of further advancement. The older operation of myomectomy, on the other hand, lagged behind. From time to time over the last 40 years a few surgeons here and there essayed it on the large scale, but their efforts as far as influencing surgical thought was concerned were barren. The greatest of these pioneers was W. Alexander, of Liverpool, who in 1897–98 in three remarkable papers[1] described a technique by which he had been able to remove successfully as many as 25 tumours from a single uterus. His innovation had a hostile reception, and it is significant that though I entered gynæcology only six months after the papers were published I never heard or saw them referred to or indeed knew of their existence until 1922 when I had occasion to look up the literature.

The Conservation of the Uterus.

Since cure without deformity or loss of function must ever be surgery's highest ideal, the general proposition that myomectomy is a greater surgical achievement than hysterectomy is incontestable. Passing from the general principle to the particular argument, we have first to consider the question of childbearing. The duration of a woman's capacity for conception varies according to whether the conception is a first or a subsequent one. For first conception 43 years of age may be taken as the practical limit, but for subsequent conception 45, so that at least up to 41 the preservation of the uterus deserves serious consideration if, as I shall presently show, pregnancy is not only possible but likely after such preservation. It is true that many women do not wish for children or more children, but that is a very different thing from desiring that the capacity for conception shall be taken away from them. The two must not be confounded. The conscious or subconscious knowledge of the power to conceive is the nucleus around which the feminine sex-emotions most commonly cluster quite apart from whether or not a child is actually desired, and the central idea being gone the emotions either wilt or transfer themselves to spheres of emotional activity other than sex. There are certain women, no doubt, in whom union with the beloved rather than the results of that union is the central idea, and to such the loss of the organ of conception will be less important in its psychic results. This is the male type of sexuality, though even in men the paternal idea bulks much larger than the individual himself is usually aware of, and when the culminating act is condemned to irrevocable futility a weakening of the sex ties is very liable to ensue. An instinctive knowledge of this fact is at the back of many patients' objection to hysterectomy, and women thus marred not infrequently develop an inferiority complex under which they magnify trivial acts of forgetfulness into intentional slights and become touchy and suspicious.

Women who have borne children, especially many children, are on the average much less likely to be adverse to the idea of losing their wombs than women who have borne none, although amongst this latter group there are many whose chances of childbearing under any circumstances are practically non-existent. The assurance afforded by the operation against any further extension of the anxieties and self-sacrifices of motherhood is no doubt partly responsible for this average difference of attitude, but beyond it I think that the parous woman feels that having borne children the perfection of her femininity needs no further proof, just as a soldier having shown his courage in the field lays by his sword without regret or misgiving. Though the majority of men when they marry do so for affection and companionship and not for the sake of having children, yet there is a certain proportion to whom the rearing of a family is the chief incentive. The value, therefore, of a woman from the point of view of marriage is definitely lowered if she is wombless. Fibroids are relatively rare in young women, yet they are not infrequently met with, and surely it is a sorry reflection on surgery if it is not able to secure health for such patients without jeopardising their future happiness, and the gynæcological surgeon, but half-sighted, who is blind to the importance of leaving intact in its fullest possible strength the tie that binds together such totally dissimilar creatures as man and woman.

There exists such diversity in feminine character that no sweeping generalisation on anything connected with the sex is possible, but this at least is true that to a considerable proportion of women the removal of the womb is repugnant either because they hope to have children or wish to maintain the possibility of having them, or fear the effect on their own affections or on those of their husbands or lovers. Women in these matters do not commonly wear their hearts on their sleeves so that the surgeon frequently has little or no knowledge of the psychology of the patient whom he is advising. It is wisest for him, therefore, in the absence of expressed opinion one way or the other, to be as conservative as possible, bearing in mind that the patient in committing to him the fate of her womb is often entrusting him with her future happiness as well.

Myomectomy.

Some 18 years ago, impelled by the considerations just set forth, I began to explore the possibilities of extending the conservation of the uterus to those cases of fibroids hitherto considered to be outside the range of conservative surgery. By 1918 I had gained experience enough to be able to show that the old limits set on myomectomy no longer obtained.[2] In 1922 a second paper[3] of mine appeared expanding the subject considerably and describing the technique of the operation with some minuteness, and in 1925 I published the results of 220 consecutive operations.[4] Five years have elapsed since then, during which period I have steadily pushed on with the work, not only to the widening of my experience and the improvement of my operative technique, but to a better appreciation of the ultimate results of the operation.

Let me remind you of the position occupied by myomectomy up to a few years ago. It was an operation whose application according to the gynæcological text-books was limited to cases in which a single fibroid was present, either stalked, sessile, or not too deeply embedded, whilst the only description of the technique to be found in any book on operative surgery was briefly how to ligature the pedicle of a stalked tumour and how to suture up a small and superficial enucleation cavity. I have altered all that, so that to-day it may be said that it is unusual to meet with a case of fibroids—no matter how numerous the tumours, how large or how placed—that is beyond the scope of conservative surgery. The dissatisfaction and regret of being compelled by the poverty of our resources to remove the uterus from a girl of under 25, or from a woman of 30 recently engaged and looking forward to the joys of maternity, or from a newly-wed wife of 35 who after years of waiting thought that her wish was going to be realised—the dissatisfaction and regret, I say, of having to do this, and in doing it act the executioner of who knows how many secret hopes and tender fancies—need be ours no longer. The surgeon, in short, has a freedom of choice and action when dealing with fibroids that he did not possess before.

RESULTS AND SEQUELS OF THE OPERATION.

From 1911 up to the end of last year I performed myomectomy 403 times. The tumours removed were solitary in 166 cases and multiple in 237 cases. The greatest number of fibroids I have removed from a single uterus is 125, and after this 92, 80, 55, 52, 48, 46, and 44, whilst on 28 occasions the number has varied between 15 and 30. It is obvious therefore that the mere quantity of fibroids contained in a uterus does not bar conservative operation. Nor does the size per se, for I have performed multiple myomectomy in cases where the total mass was about that of a full-term pregnancy. The ease or the difficulty of the operation depends less on the size and the number of the tumours than on the position they occupy in the uterus. Thus, a tumour of the lateral wall is more troublesome to remove than one in the anterior wall, and a tumour in the posterior wall more difficult than either. I shall return to these points later.

Operative Mortality.—There have been seven deaths in the series, an operative death-rate of 1·7 per cent. This is much about the same mortality as attaches to hysterectomy for fibroids when carried out by surgeons expert in that operation. The causes of death were as follows: One patient succumbed to secondary hæmorrhage, unfortunately not detected until too late. A technical fault was involved here. One death was due to necrosis of part of the uterine wall caused by the over-use of matress sutures. Two patients died of paretic intestinal obstruction, the cause of which I much suspect was the same technical fault. There was one death by pulmonary embolism, the woman up to that moment having been perfectly well. Finally, there were two deaths due to hæmorrhagic shock which specially deserve attention. Both patients had large multiple fibroids and in addition were pregnant, the one about six months and the other at term. In order to remove the child it was necessary in both cases to cut into a mass of fibroids on the anterior wall of the uterus, and the incisions and subsequent enucleations were accompanied by bleeding of great violence. I shall come back to these cases presently.

Late Results.—Excepting in the case of operations performed in the last two years I wrote to all my patients' medical men, or where there was no medical man to the patients themselves asking: (1) the effect of the operation on the periods, (2) the necessity or otherwise for further operation, (3) whether the patient had been pregnant since the operation, and (4) the effect of the operation on the general health. Considering that many of the women had been operated on in hospital years ago, since when I had had no communication with them, the 210 replies received were more than I expected. The reports on the whole are surprisingly satisfactory and much beyond my anticipation, although I knew beforehand that the results were good, for no surgeon can go on performing a number of operations whose results are unsatisfactory without in a short time becoming acutely aware of his failures which, like other sins and deficiencies, presently come home to roost.

Menorrhagia.—Out of these 210 cases menorrhagia either persisted after the operation or recurred ten times. Five of the patients (three of whom had new fibroids) subsequently underwent hysterectomy; one was curetted, and two had intra-uterine polyps removed. The remaining two have had no further operation.

Development of New Fibroids.—Eight of the 210 patients developed new fibroids after the operation. Two have required no further operation, the recurrent tumours being small. The particulars of the six who developed new fibroids and underwent a second abdominal operation are as follows:—

Patient.	Age.	Fibroids originally removed.
No. 1	19 years	92
„ 2	23 „	52
„ 3	29 „	4
„ 4	30 „	8
„ 5	29 „	17
„ 6	36 „	14

---

[2] Brit. Med. Jour., 1918, i., 278.

[3] Jour. Obst. and Gyn. Brit. Emp., 1922, xxix., and THE LANCET, 1922, ii., 745.

[4] Brit. Med. Jour., 1925, ii., 951.

It will be perceived that this group contains two very exceptional cases—in particular the girl of 19, from whose uterus I removed 92 fibroids. When fibroids are developed at such an unusually early age a special tendency to the formation of such tumours must be inferred, and therefore the chance of new fibroids forming must be very considerable, not only because the patient has more years before her in which to form them but also because the uterine tissue itself is in its fibroid-forming tendency peculiar. My experience leads me to believe that the tendency to the formation of these tumours is a passing phase in the uterine tissues and not a continuous defect, for otherwise myomectomy would be bound to fail in a very large proportion of the cases, whereas, in fact, recrudescence is, as I have shown, quite rare Such a passing phase is paralleled in gall-stone formation. If the tendency to form calculi was a permanent defect of the gall-bladder, cholecystotomy would be bound to fail every time, for new calculi would begin to form from the very moment the old ones were extracted. That new calculi do sometimes form is true, but with nothing like the frequency that a permanent calculus-forming habit of the gall-bladder would demand.

In the case of the uterus I believe that in most instances the nuclei of all the fibroids a woman is ever going to grow are laid down by the time she has reached 30 years of age, or but very little over. It follows that when myomectomy is performed on patients in the twenties or early thirties the fibroid-forming tendency of the uterine tissues has not yet gone into abeyance and the chances of the formation of new tumours is on this account considerably greater than when the operation is performed on patients over 34 years of age, especially when the number of tumours removed at the first operation has been considerable. On the other hand, it is just in these exceptionally young patients that the desirability of saving the uterus is greatest, and if surgery can restore their marriage value for even a few years, or, better still, enable them to have even one child, no inconsiderable gain is effected even though in the end hysterectomy becomes inevitable.

The details of the subsequent operations of these six patients are as follows. The first three developed new fibroids very quickly, and all of them in from two to five years had to have the uterus removed. The fourth patient conceived after the myomectomy, and during the pregnancy new fibroids were felt in the uterus. She delivered herself naturally, and then returned to the hospital for removal of the new tumours which were obviously growing. She was anxious, however, not to have any more children as she already had three, and hysterectomy was carried out though re-myomectomy would have been equally easy. The fifth patient was very anxious to conceive but did not do so although at the time of the myomectomy the tubes and ovaries were normal. Eight years after the operation she had severe pains which were attributed to appendicitis. I reopened her and the cause of her sterility was revealed in extensive endometriomatosis of both ovaries. I enucleated the blood cysts and, finding a few small new fibroids in the uterus, enucleated them also. She is now 38 but has not conceived. The sixth patient conceived of her first child eight years after the myomectomy; I delivered her by Cæsarean hysterectomy, several new fibroids having developed in the uterus, and the patient being in her forty-fifth year.

General Health.—The health of the 210 women concerning whom information was received has, apart from the ten instances of recurrence of the menorrhagia, been very good indeed. Of only two of them is it stated that their general condition is poor. Two other women besides the one already mentioned had been operated on for endometriomatous cysts of the ovary subsequent to the myomectomy but without the finding of any more fibroids. It is possible that fibroids may promote endometriomatosis—at all events, the two conditions are not infrequently found together.

Pregnancy after Operation.—Of the 210 patients from whom replies have been received 120 were at the date of their operations under 41 years of age, whilst 90 were over that age. Of the 120 under 41 years of age 33 have remained either unmarried or widows, whilst nine stated that pregnancy had been prevented, and one patient had her tubes tied at the operation. These being subtracted there remains a group of 77 married women within the childbearing age at the time of the operation and wishful to conceive after it. Of this group no less than 30, or 39 per cent., did conceive after the operation. Twenty-six of them conceived once (one with twins). Two of them conceived twice, and two of them conceived three times. The manner of their deliveries is as follows: Of the 26 who conceived once 18 delivered themselves naturally, five were delivered by Cæsarean section, one by Cæsarean hysterectomy, and two miscarried. Of the two who conceived twice the deliveries were all natural. Of the two who conceived three times the deliveries in one case were all natural, but in the other the first child had to be perforated for contracted pelvis, after which she had two further deliveries by Cæsarean section.

Altogether 36 live children have been produced by these women, and to this gain in infant life must be added seven cases in which, when performing myomectomy on a pregnant uterus, I conserved the child within the uterus so that it was delivered in due course at term.

SUMMARY OF RESULTS.

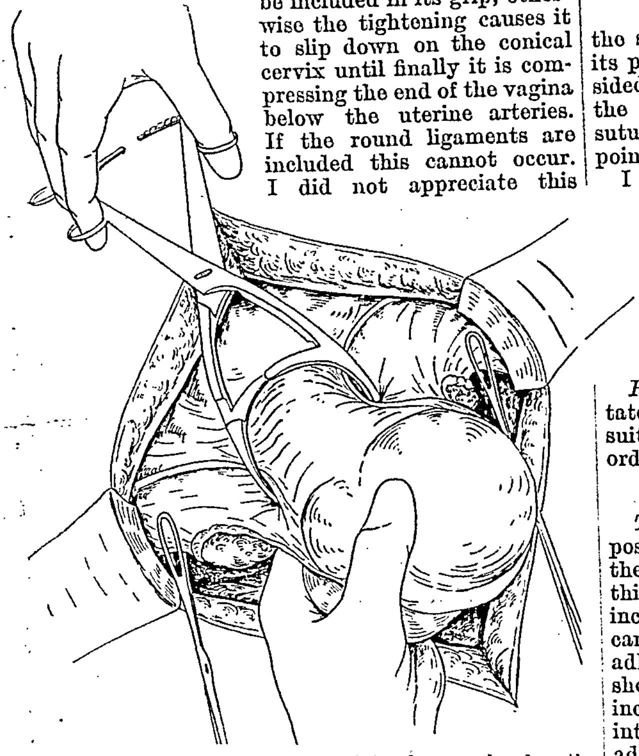
At the beginning of this paper I remarked on the slow development of myomectomy as compared with other standard abdominal operations. Three objections levelled against it have been responsible for this. The first objection was that except when restricted to a very special and small group of cases it was a much more dangerous operation than hysterectomy. The second asserted that the excessive loss at the periods about which most women possessing fibroids come complaining would probably continue after the operation. The third alleged that a uterus from which a deeply embedded fibroid and, still more, multiple fibroids had been enucleated would be of little use for childbearing and would be a danger in the event of conception. The figures I have laid before you to-day will, I hope, dispose of these objections for good and all. The operative mortality of myomectomy need be no greater than that of hysterectomy—i.e., somewhere between 1 and 2 per cent. The proportion of cases in which, subsequent to myomectomy, menorrhagia due either to new fibroids or to other causes compels eventual hysterectomy is 3 per cent. Of women who have undergone myomectomy and are within the age for childbearing and wishful to have a child, 39 per cent. may be expected to conceive. Of the children born after the myomectomies performed by me 75 per cent. were born naturally, and more could have been born so only that certain of the mothers having already experience of an abdominal operation elected to have the child delivered by Cæsarean section in order to give it the best possible chance of surviving.

Technique of the Operation.

Asepsis.—In no operation is asepsis of more importance, for the total extent of the rawed surfaces is often considerable and the number of sutures used very large. I cover the edges of the abdominal wound with two layers of sheet rubber and also pack the uterus round so as to completely isolate it. The catgut must be irreproachable on account of the amount buried, and in this matter I am grateful to Prof. W. Bulloch for having invented Chorda catgut.

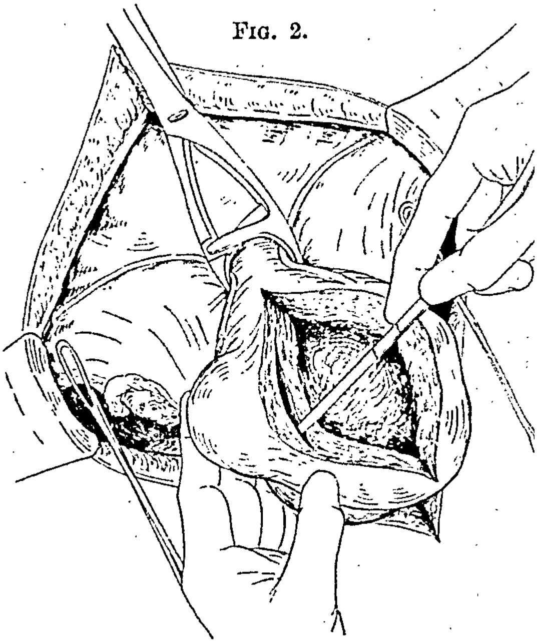
Hæmostasis.—The main drawback to the operation in the past was the bleeding from the uterus over which the surgeon had no control. For myomectomy to be ideal it requires to be almost bloodless, for anything like profuse oozing so blinds, hampers, and hurries the operator that the removal of the fibroids and the reconstruction of the uterus afterwards cannot be neatly done. Nine years ago I designed a clamp (Fig. 1) which compresses both uterine arteries at once, so that with a ring forceps on each ovario-pelvic ligament all the four main arteries of the uterus are blocked and the operation is carried out on an almost bloodless organ. This advantage has revolutionised the operation as far as its ancient difficulty was concerned, for the operator can work as deliberately as he chooses, and if finally he finds that he cannot make a satisfactory job, the patient, who has lost practically no blood, is in perfectly good condition for hysterectomy. The clamp is applied from the pubic end of the abdominal wound, and it is essential that the round ligaments should be included in its grip, otherwise the tightening causes it to slip down on the conical cervix until finally it is compressing the end of the vagina below the uterine arteries. If the round ligaments are included this cannot occur. I did not appreciate this when I originally designed the instrument, with the result that the blades as first made are too small. The clamp and the forceps on the ovarian vessels are not removed until the suturing of the uterus is completed. When they are taken off the uterus flushes up like a limb after a tourniquet is removed and the immediate effect is a certain amount of oozing from the suture holes. The uterus should be returned its place and let to lie there until the flush has s sided, after which it will probably be found t the oozing has ceased. If it has not, an additional suture or two should be inserted at the oozing points.

FIG. 1.



Applying the myomectomy clamp. Ring forceps placed on the ovario-pelvic ligaments.

FIG. 2.



Making a secondary incision to remove a lateral fibroid.

I have frequently been asked whether the clamp may not damage the uterine vessels and promote thrombosis and embolism. The happening is imaginary, for the vessels are too well protected by the tissues in which they are embedded. The one death I have had from pulmonary embolism in my series is no more than might have occurred if the operation had been hysterectomy instead of myomectomy.

Reverdin's Needle.—The operation is much facilitated by the use of this instrument, which is better suited for the insertion of deep mass sutures than the ordinary surgical needle.

INCISIONS AND SUTURES.

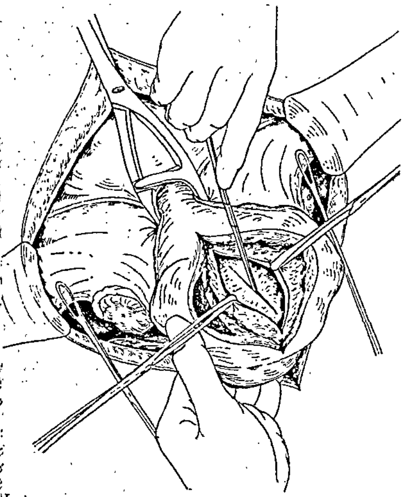
The Primary Incision in the Uterus.—Whenever possible this should be single and median through the front wall of the uterus. Alexander enunciated this principle in 1898. The reason is that every incision through the peritoneal coat of the uterus carries with it the risk of post-operative oozing and adhesion afterwards. The number of such incisions should therefore be kept as low as possible. An incision in the front wall, if it oozes, merely does so into the utero-vesical space and only the bladder adhere, whereas one on the posterior wall oo directly into the general peritoneal cavity and i adhesions form small intestine is the most likely thing to adhere. Another great advantage of the anterior incision is that if it seems desirable the surgeon can bring it up against the anterior abdominal wall by ventrofixing the uterus along the line o suture, or he can oppose it to the posterior surface of the bladder by shortening or pleating the round ligaments or by the "sling" operation; or he may cover it by a flap of peritoneum brought up from the lower uterine segment. The covering of a posterior incision so as to protect against the risk of intestinal adhesion is less easy to effect.

Secondary Incisions.—Tumours not directly accessible through the median anterior incision are reached by secondary incisions. As Alexander pointed out, fibroids are sufficiently movable in the uterine wall to allow of their being pushed towards the opening through which it is desired to extract them. Thus not only anterior fibroids off the middle line, but fibroids lying in the lateral walls and even (if not too large) in the posterior wall can be pushed round to meet a side track made by the scalpel from off the primary incision (Fig. 2).

Tumours in the Posterior Wall.—Many posterior fibroids, especially if large, cannot be reached this way. In cases of this sort the surgeon must adopt either what I call "transcavity enucleation" or perform the "hood operation."

On Opening the Uterine Cavity.—In the majority of cases of myomectomy it is desirable to open and explore with the finger the uterine cavity, for otherwise it is quite easy to miss a small submucous fibroid or a mucous polypus and thus perhaps leave behind the chief cause of the menorrhagia for which the operation is being carried out. The opening of the cavity will not increase the risk of the operation unless the uterus is already infected, in which event myomectomy should never be attempted.

FIG. 3.

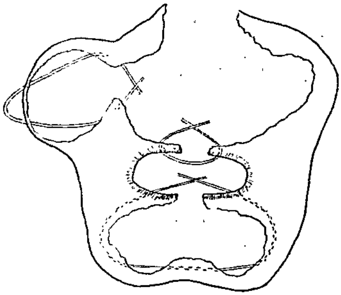


Incising the posterior endometrium over a posterior fibroid.

"Transcavity" Enucleation.—The cavity of the uterus is opened through its front wall either by incising the bed of the anterior enucleation cavity if there is one, or by deepening the primary anterior incision if there is not. The cavity having been explored, its posterior wall is incised over the fibroid, which is then enucleated into the cavity and so out through the primary anterior incision (Fig. 3).

Reconstructing the Uterus.—A uterus in which is embedded a fibroid or fibroids of any considerable size is more or less hypertrophied, so that after the tumours are removed an organ is left of abnormal bulk. Involution occurs after myomectomy as after pregnancy, but not so vigorously, so that some reduction in its size depending on the degree of hypertrophy is advisable before it is finally sutured. To return to the abdomen an organ free of fibroids, but so large as to be beyond the capacity of involution, is to run the risk of menorrhagia persisting after the operation. Moreover, a very bulky uterus is not only more difficult to suture but carries with it an increased risk of post-operative oozing. A certain amount of the uterine tissue therefore needs to be cut away in many cases. The degree and fashion of removal is a matter of judgment, and, moreover, the hypertrophy is often unequally distributed. The surgeon in doing it therefore must have regard to certain fixed points, like the roots of the tubes and the take off of the round ligaments, otherwise he will find he has fashioned an asymmetrical organ.

FIG. 4.



Methods of suturing enucleation cavities.

Suture of the Enucleation Cavities.—To obliterate the enucleation cavities catgut should chiefly be employed, silk being reserved for points where considerable tension is thrown on the tissues. In my earlier papers I advocated the free use of matress sutures. It was a mistake, as this form of suture interferes with the blood-supply of the tissues superficial to the suture, and I lost one case from necrosis of the uterine wall in consequence of this. I now only employ matress sutures sparingly and often not at all. For the closure of median anterior cavities I use a row or sometimes tiers of simple through-and-through sutures, and finish off the superficial part of the incision by a continuous stitch. Anterior cavities off the middle line can usually be included by the through-and-through sutures, especially if part of the anterior wall has been cut away. Cavities in the lateral wall can often be obliterated by separate sutures passed through the tissue that surrounds them and tied across the mouth of the cavity. When, however, the cavity approaches very close to the peritoneal surface another device is required. A suture is passed from the cavity through the peritoneum forming its floor and then back again, the two ends are then passed through the stouter tissues bounding its mouth so that when the suture is tied the peritoneum is drawn into the cavity and obliterates it. Several of these sutures may be used. Cavities in the back wall whose mouth opens out on to the posterior endometrium after "transcavity enucleation" can be closed by sutures passed through the tissue surrounding them and tied on the endometrial surface. The knots are well tolerated. If, however, as already described for lateral cavities, the peritoneum has been closely approached, the inturning device should be applied (Fig. 4).

The Hood Operation.—When a fibroid in the posterior wall is too large for "transcavity enucleation" the following technique may be adopted. An incision is made transversely across the uterus just posterior to the line of the tubes, and the capsule of the tumour having been opened it is enucleated. The portion of the uterine wall that covered it now hangs down behind, like the hood of a monk when it is thrown back off the head. By means of several series of sutures this hood is now brought forwards over the fundus and down the anterior wall, until when the suturing is finished the whole of the superficial suture line lies U-shaped on the anterior wall with its lowest point just above the bottom of the utero-vesical pouch. The hood is almost invariably thick and requires a good deal of planeing away before it fits over the uterus neatly. This is a very pretty and successful operation, and avoids the long incision down the posterior wall which a direct approach to the tumour from that surface would entail (Fig. 5).

FIG. 5.

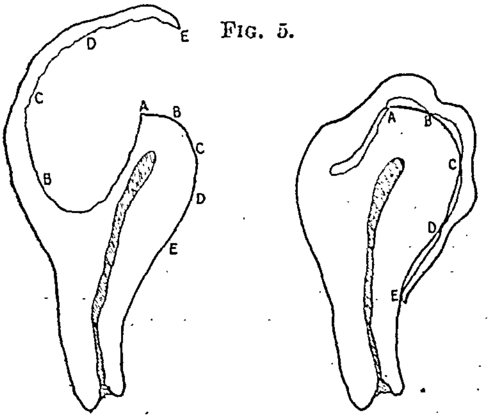


Diagram to illustrate the hood operation.

Posterior Primary Incisions.—There are some posterior fibroids that cannot be extracted through an anterior incision, most notably small ones that lie immediately under the peritoneum. These have to be removed by an incision over them. The best way to close these cavities is to place a purse-string suture around but some little distance from their mouth. The suture when tied invaginates the peritoneum which obliterates the cavity and leaves nothing on the posterior peritoneal surface but the knot. Occasionally, however, all such devices fail, and a sutured wound has perforce to be left fronting back on the intestines. If it is situated low down the best thing is to attach the pelvic colon to it lightly by a few catgut sutures as the adhesion resulting will do no harm. If, however, the uterine wound is too high up for this the mesosalpinx or even the whole appendage may be swung in and sutured to it so as to cut it out from the general peritoneal cavity.

MYOMECTOMY BY BLOCK EXCISION.

There are certain cases in which the uterus is beset with so many fibroids that none of the foregoing devices is applicable. In such, if myomectomy is decided upon, the method of block excision is available. The surgeon, having secured all four arteries as already described, splits the uterus into two halves by a median sagittal incision. The opened cavity having been examined he now, with a finger passed into one cornu, makes certain of the line in which the interstitial portion of the tube is running, and then proceeds to cut away a wedge-shaped mass which includes both uterine wall and its contained fibroids. Before cutting it away he should mark out with the scalpel the line along which he intends to cut, paying attention to the position of the round ligament and the root of the tube. He then repeats the proceeding on the other side. The uterus now consists of two much reduced halves from which perhaps a few more fibroids need picking out. These halves he then proceeds to suture together. The sutures uniting the posterior wall should be tied on the peritoneal surface, but the posterior endometrium should be separately united by a series of sutures tied on the mucous surface. Similar sutures, but tied in the depths of the anterior wall, close the anterior endometrium, and then the anterior wall itself is sutured. Finally a continuous suture is inserted beginning at the lower end of the incision on the posterior wall and continued over the fundus down the anterior wall. This operation, which is a derivative of utriculoplasty, enables a very large number of tumours to be dealt with adequately, but it has the disadvantage of leaving a great length of suture line opposed to the intestines.

CERVICAL FIBROIDS.

A fibroid growing in the supravaginal cervix prevents the clamp that secures the uterine arteries being applied and therefore makes the case more difficult for myomectomy. If the tumour is not large and there are others in the uterus, that in the cervix should be enucleated first, after which the clamp can be applied and the others removed. When, however, the cervical fibroid is large and of the variety called "central" the problem is much more serious, because in addition to the hæmorrhage it is difficult to deal with the immensely elongated and hypertrophied cervix that remains after the enucleation. If myomectomy is decided on the best technique is to clamp both the ovarian and the uterine arteries on either side by long slender bowel clamps applied from the tops of the broad ligaments downwards. The uterine arteries being considerably raised by the tumour below them enables this to be done. The loose peritoneum on the front of the uterus should then be reflected back, and the bladder with it, after which the uterus should be incised medially from the fundus down to the capsule of the tumour. If possible this incision should be limited to the anterior wall, but it may be necessary to bisect the uterus. The fibroid is then shelled out and as much as seems necessary of the redundant tissue of the cervix cut away. Great care must be exercised in doing this not to injure the bladder or the ureters. The remainder of the cervical tissues is then drawn together with sutures placed wherever possible so as to shorten the cervix. All bleeding having been stopped, the uterus above is sutured and the peritoneal flap brought back so as to cover most of the suture line. Myomectomy may be a formidable operation in cases of central cervical fibroids such as I describe. Fortunately they are rare.

Myomectomy on the Pregnant Uterus.

Conservation is most of all merited when the uterus is pregnant, for then the proof of its functional value stares the surgeon in the face. Where the child is not yet viable and the fibroid or fibroids are conveniently placed and not too numerous they may be removed without disturbing the pregnancy. A miscarriage may ensue, but it is remarkable how rarely this happens. Nine is the largest number of fibroids I have been able to remove and leave the pregnancy intact. When, however, the tumours are many and ill-placed, it is impossible to enucleate them without first removing the pregnancy. Several women on whom I thus operated had a living child afterwards.

If the child is viable it should be delivered through the primary incision before touching the fibroids so that the myomectomy clamp can be applied before the enucleation is started upon. In many of these cases the procedure is quite straightforward, but there are others in which careful consideration is required before starting on the conservative operation, notably those in which to get at the child it will be necessary to cut through a large mass of tumours in front of it. Under such circumstances the uterus may be immensely hypertrophied and vascular, and as the head of the child prevents the myomectomy clamp being applied a great quantity of blood is lost in a very short time. I have already referred to the two fatalities in my series due to this cause. If myomectomy is decided upon, the uterus should be eventerated first, and after the ovarian vessels are secured by forceps, an area in the fundus clear of tumours should be sought for, and the child extracted through it, after which the myomectomy clamp can be applied and the removal of the placenta and fibroids proceeded with. If the surgeon has any doubts as to his ability to carry the operation through or the patient's capacity to stand it, hysterectomy should be done.

Conclusion.

My statement that cases of fibroids beyond the scope of conservative surgery are uncommon must not be interpreted to mean that myomectomy is the operation of choice in the majority of patients suffering from these tumours. Myomectomy varies immensely in magnitude in different cases, being sometimes much easier than the corresponding hysterectomy, and sometimes much more difficult. For women over 41 years of age it is only to be preferred to hysterectomy when obviously the lesser operation of the two, or when the patient for reasons of her own wishes it. For women of 41 and under it should, broadly speaking, be the operation of choice, but there are exceptions. The patient may desire the removal of the uterus either to free herself of the possibility of conception or to escape the monthly annoyance or pain of the periods, or she may present such extreme anæmia as to render continuance of the menses (however scantily) undesirable.

Myomectomy should not be performed unless the uterus, apart from its contained fibroids, is reasonably healthy, nor ever unless the surgeon feels sure that the fibroids themselves present no suspicion of malignancy. Of this last possibility I had a sad lesson. I was asked to perform myomectomy on a young and attractive lady. I removed a number of tumours and noticed that they had an unusually glassy appearance, but the pathologist merely reported a high degree of degeneration. As the event proved, they were sarcomatous and very rapid recurrence took place of which she died.

The various forms of non-malignant degeneration—"red" myxomatoid, hyaline, cystic, nævoid, and so *forth—do not in the least contra-indicate conservatism*, and this is specially noteworthy of "red" degeneration with which pyrexia is so often associated. I have with impunity enucleated such fibroids on many occasions.

Summing all these considerations, the one against the other, it is apparent that whilst hysterectomy is still the operation most frequently called for in the treatment of fibroids the sphere of myomectomy is a large and very important one. Despite, however, the fine work of Leith Murray[5] and certain other gynæcological surgeons who have done me the honour to follow my lead, this fact is very inadequately recognised so that, taking surgical practice at large, a number of women yearly are still condemned to lose their wombs when the equally safe and more beneficent operation of conservatism should be in the surgeon's repertory. A procedure which on technical grounds alone affords an opportunity for individual ingenuity and craftsmanship compared with which routine hysterectomy is as mere mass production should need no urging. The barriers set round myomectomy in the past have been swept away *and a new territory is added to the domain of* surgery for those who will enter on it.

ÆTIOLOGY OF PEPTIC ULCER.*

By Laurence O'Shaughnessy, F.R.C.S. Eng.,
Sudan Medical Service.

Some two years ago two articles on the treatment of peptic ulcer appeared in the same number of a current medical journal. In the first, an eminent physician proclaimed that cure was possible by medical means and, except in rare cases, deprecated any surgical interference. In the second, an equally eminent surgeon insisted on the necessity of surgery, and surgery of a much more radical type than had been the custom—partial gastrectomy in place of gastro-enterostomy. This violent discrepancy of opinion would seem to justify yet another addition to an already vast and unwieldly literature.

Since it is impossible to give within the confines of this paper even a brief summary of all the literature, I only propose to set out the impressions formed by a fairly extensive study of recent communications.

Although the site of a peptic ulcer is of obvious clinical importance, the factors concerned in its production and behaviour seem to be the same whether it is found in the stomach or duodenum, at the site of a gastro-jejunal anastomosis or even in a portion of ileum which contains, by some strange developmental error, a segment of gastric mucosa—it is an ulcer arising in an area bathed by an acid juice containing the ferment pepsin.

* Abstract of a Stephen Scott Essay, University of Durham College of Medicine.

Review of Experimental Work.

ACUTE ULCER.

It is stated by Pulvertaft[1] that there are at least 50 methods of inducing acute gastric ulcer in the rabbit, and that, in addition, spontaneous ulcers are not infrequent. This is in striking contrast with the difficulty of producing chronic ulcers experimentally. It does not seem helpful to use the various synonyms—"erosion," "hæmorrhagic erosion," and so on—for acute ulcer, and those terms will not appear further. In most, if not all, experimental ulcers the initial lesion is a submucous hæmorrhage which tears off part of the mucosa; this is followed by the eroding action of the peptic juice, a small-celled infiltration, and, if the animal survive, healing by fibroblastic cells and regeneration of the mucosa. All these stages have been observed by many workers, but the methods of their production have been varied in the extreme.

As early as 1857 Lebert produced acute ulcers of the stomach as part of a general pyæmia, and since this time the oral, intravenous or intraperitoneal administration of the most diverse organisms, ranging from a hæmolytic streptococcus to a meningococcus, has produced similar results. There is a close parallel between these experiments and the acute ulcer appearing in man as an incident in a generalised infection which may also be of the most varied description, from pulmonary tuberculosis to streptococcal septicæmia.

Perhaps the most interesting method of inducing acute ulcer is that devised by Bolton,[2] who employed local injection of gastrotoxic serum. A serum active against the guinea-pig was prepared by injecting a rabbit with the gastric cells of a guinea-pig, and a similar serum active for the cat was produced from a goat. The principle of cytotoxins has been very fully worked out, but at the moment throws little light on the ætiology of ulcer in man. Ultimately it may be possible to trace the relationship between gastrotoxic serum and histamine, a natural product of protein disintegration. McIlroy[3] reported acute ulcer in the stomach of a cat which had been given subcutaneous injections of histamine for some other purpose. He also showed that histamine produced some extension of lesions artificially induced in the gastric mucosa, although he failed to produce anything like a chronic ulcer. Büchner[4] obtained acute ulcers in rats by a combination of starvation on alternate days and histamine injections. My own experience of histamine is detailed below. The action of histamine is not fully understood, but it is clear that it has a specific dilator action on capillaries, and also that it increases gastric acidity.

Acute ulcers have been reported after stimulation of the sympathetic, and it is even suggested that ulcers which have followed pyloric occlusion and the more radical surgical procedures of Mann are due to some interference with the nervous control. This suggestion far outstrips the evidence, especially as the splanchnic nerve, although it conveys motor impulses to the pylorus, is inhibitory to gastric secretion. Sherren[5] states that "interference" with the vagi produces acute ulcer, but no definite evidence on the point seems to exist and the results of section of these nerves fail to support this view.

Acute ulcers have frequently been produced by such diverse procedures as adrenalectomy, thyroidectomy and partial hepatectomy; but the rationale of all these experiments is that such radical operations cause extreme debility, and that there is a high incidence of acute ulcer in weak and debilitated animals from whatsoever cause.

Magee[6] has produced acute ulcer in cavies by diets deficient in inorganic constituents and vitamins. It seems desirable to regard the acute ulcer of the rabbit and cavie with suspicion, but his results are of especial interest, as the animals showed changes in the adrenals ranging from congestion to frank hæmorrhage.

CHRONIC PEPTIC ULCER.

The means of producing chronic ulcer in animals are as few as the means of producing acute ulcer are many. The tendency of all acute lesions in the stomach is to heal and, although Bolton and others delayed the healing of acute ulcer by such measures as inducing pyloric stenosis or giving acid, they consistently failed to produce a true chronic ulcer.

Dott and Lim[7] and also von der Hutten produced gastro-jejunal ulcers of chronic type in dogs by the operation of pyloric occlusion and gastro-enterostomy. Mann and Williamson,[8] working with dogs and cats, produced ulcers in the duodenum and jejunum by diverting the alkaline secretions into the lower ileum, where they could not neutralise the gastric acid. Ulcers occurred in 90 per cent. of cases and were probably more like clinical peptic ulcers than any experimental lesion previously described. This operation is described as duodenal drainage. Morton[9] extended the work by excising portions of gastric mucosa in addition to carrying out duodenal drainage. He found delay in healing in 100 per cent. of cases and ulcer in 50 per cent., but these ulcers do not appear to have had the same definite characteristics as those described by Mann.

Although this method is of interest, as enabling the behaviour of peptic ulcer and its response to various therapeutic measures to be studied experimentally, it appears to throw little light on the true ætiology of peptic ulcer in man. Hyperacidity is only the factor which may delay healing, not the initial cause; and the measures adopted to secure this hyperacidity involve a distortion of the normal alimentary mechanism so gross that it can never be paralleled in man. Malnutrition can, in itself, produce ulcer in animals, and Mann admits an initial post-operative loss of weight of 10 per cent. followed by a much greater loss as the animals developed ulcer. This secondary loss of weight is attributed t the effect of the ulcer, but it may be the natura result of malnutrition. It is also possible, as points out, that local malnutrition of the intesti wall, due to interference with its blood-supply, is importance. The operation of duodenal drainage of necessity associated with much trauma, and it tempting to regard histamine, a constant product such trauma, as an associated factor, but at prese this may be a fantastic hypothesis.

Rosenow,[13] who maintains that chronic ulcer c be produced by the injection of streptococci, remai undeterred by this work and is endeavouring isolate his streptococcus from the ulcers of duoden drainage, but his results are not so far available.

Clinical Aspects.

ACUTE ULCER.

The ætiology of acute ulcer, arising as an incide of infection, seems to be fairly clear, but the cause acute ulcer as a symptom-complex *sui generis* is greater problem. Acute ulcer frequently occurs anæmic and poorly-nourished women, but all suc women do not suffer from ulcer, and clearly some yet unknown factor must also be concerned. Oral sepsis is by no means an invariable accompaniment and, even if it is present, there is no proof that it has any specific effect on the gastric mucosa; it may merely have contributed to the general state of debility.

The acute ulcer following burns is of especial interest in view of the experimental lesion following the use of histamine, as it is presumably due to the absorption of toxic products of protein disintegration. Harris[10] reports a case in which an acute duodenal ulcer, together with a large hæmorrhage into the suprarenal gland, resulted from an extensive burn in a child. Possibly the adrenal hæmorrhage may be interpreted as the result of intense activity of the gland in its effort to compensate for the various toxic products from the site of the burn. Adrenal hæmorrhages were associated with the ulcers produced by Magee in his dietary experiments and in one of the histamine experiments described below. These rare ulcers have usually been found in the duodenum, but D'Ewart[11] describes a case of gastric hæmorrhage following burns in a child. He makes no mention of the condition of the adrenals, and states that the gastric mucosa showed no ulcer but merely punctiform hæmorrhages; but frequently in such cases ulcer can be seen only by careful search with a hand lens, and this does not seem to have been carried out.

CHRONIC ULCER.

The first problem is to decide the relationship, if any, between acute and chronic ulcer, but at present it seems impossible to infer with any certainty that the chronic ulcer is an acute ulcer of which the healing has been prevented by hyperacidity or other means. The comparatively small area of the stomach and duodenum affected by chronic ulcer, and the fact that the lesion is frequently solitary, might suggest that chronic ulcer is a disease *sui generis.* On the other hand, it may be that the special conditions existing in the ulcer-bearing area are of such a nature that acute ulcer, while healing readily in other sites, fails to do so if implanted in this area.

Wilkie[12] believes with Rosenow that streptococci are the cause of chronic ulcer. He has found these organisms in the teeth, gall-bladder and appendix of patients afflicted with the disease, and has also isolated the organism in pure culture from the base of the ulcer. The ulcer-bearing area contains a large number of lymph follicles, which he regards as providing a nidus for the original infection, inviting a tempting comparison with a similar anatomical arrangement in the appendix, and he believes that the relatively fixed mucosa and precarious blood-supply serve to prevent healing. These facts are very impressive, but he has so far failed to demonstrate a selective affinity of this particular streptococcus for the stomach and duodenum by animal experiment.

Many observers have reported cases of ulcer in which no infection of the teeth, gall-bladder or appendix could be found, and Wilkie himself could not demonstrate them in all cases. It can also be urged that sepsis can act as a predisposing cause as well as an activating agent, and both clinically and experimentally it is clear that ulcer is more likely to occur when the general health is impaired. Modern bacteriological work seems to show the universality of the streptococcus, and there are few people from whom the bacteriologist is unable to obtain a streptococcus from the urine or fæces if not from the mouth or throat. The essential point is to establish the pathogenicity of organisms so recovered, and so far as ulcer is concerned this has yet to be done.

The following statement was made by Rosenow[13] as long ago as 1916, and seems to have settled the problem.

> "Peptic ulcers produced by the injection of streptococci resemble those of man in location, gross and microscopical appearance, and in that they tend to become chronic, perforate or cause hæmorrhage. Streptococci having a characteristic affinity for the stomach and duodenum have been repeatedly isolated from various foci of infection in patients with ulcer and from ulcers themselves. The organisms tend to disappear from the circulation and do not commonly produce marked lesions elsewhere. The organisms have been isolated from ulcers in animals and ulcer has again been produced on their re-injection. Filtrates of these cultures have no special tendency to produce ulcer."

These conclusions are not accepted by all. The search for the septic focus is, of course, sound, as septic foci are better eradicated, but it is probably well to retain an open mind as to their ætiological significance.

GASTRO-JEJUNAL ULCER.

There is considerable dispute as to the frequency of this condition, but Moynihan, in his résumé of the recent collective investigation of peptic ulcer, estimates it as at least 10 per cent.

Finney,[14] with a great experience of gastric surgery, has definite views on the ætiology of this form of ulcer, which he attributes solely to imperfect technique, and it may be of interest to quote the following:

> "By imperfect technique is meant the abuse of clamps in making the anastomosis; the faulty control of bleeding; faulty asepsis; hæmatoma of suture line; the development of kinks and adhesions; in short, the presence of any factor tending to impair the circulation of a localised area of intestinal wall."

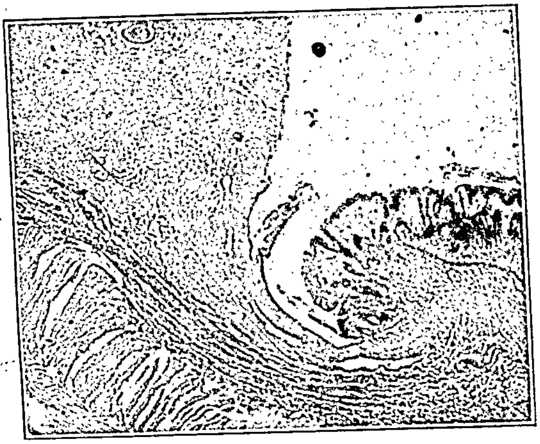
Sherren, also with a large experience, found that jejunal ulcer only resulted in cases where the pylorus had been artificially occluded. He stresses the importance of dealing with any obvious sepsis in the appendix and gall-bladder at the time of the short-circuit operation. Paterson claims that jejunal ulcer has never resulted in his own cases when appendicectomy has been combined with gastro-enterostomy. Wright[15] considered that action of gastric secretion on the jejunal mucosa was the main factor, with the following errors in technique as less important causes: clamps, injudicious feeding, and unabsorbable sutures. Lewisohn,[16] on the other hand, found that in a group of 68 cases the incidence of jejunal ulcer was slightly higher in those cases where pyloric occlusion was *not* carried out. He also states that recent improvements in technique—such as the use of welded needles—all designed to reduce tissue trauma, have not lowered the incidence of jejunal ulcer, which he attributes solely to persistent hyperacidity.

It is to avoid hyperacidity that most continental surgeons carry out partial gastrectomy on all cases of ulcer, but even after this manœuvre secondary ulcer has been reported. Nothing less than complete immunity from jejunal ulcer would seem to justify this extreme measure. If hyperacidity is the cause of jejunal ulcer, it might be expected that portions of jejunum grafted into the stomach would show a high incidence of ulcer, but actually they do not. Until 1927 this experiment had been carried out frequently with negative results, but in that year Takats and Mann,[17] by placing their graft in the ulcer-bearing area, obtained three ulcers out of 25 experiments. This low number of positive results might suggest deficient local vascular supply as a possible cause, and the manipulations are so extremely delicate that it is difficult to exclude this factor. In one of my own experiments an artificially induced ulcer on a jejunal graft placed in the ulcer-bearing area healed perfectly in less than a month.

The experimental ulcers produced by Mann after duodenal drainage and by Dott and von der Hutten after exclusion of the pylorus definitely support the hyperacidity theory. The pylorus admits acid chyme to the duodenum in a periodic manner, allowing time for neutralisation to occur, whereas the stoma of a gastro-enterostomy has no such selective action. It is also claimed that the stimulus for secretion of the alkaline juices is the presence of acid chyme in the duodenum, although more recent work seems to diminish the importance of this process. It is of interest to note that no case of secondary ulcer has ever been reported after pyloroplasty. On the other hand, attention has been drawn to the fact that duodenal drainage does considerably more than give the acid free play, and the work described below on pyloric occlusion in the cat did not confirm the results of Dott and von der Hutten.

After most careful consideration of the available evidence it seems reasonable to suppose that gastro-jejunal ulcer is due to the continued operation of the unknown ætiological factor of peptic ulcer. Attempts may be made to control post-operative acidity by suitable diet and drugs, or by the more heroic method of gastrectomy, but this factor remains, and jejunal ulcer continues to arise. It is, of course, clear that hyperacidity favours ulcer, and therefore attempts to control it are laudable; it is not contended that tissue trauma or bad technique are of less importance in gastric surgery than elsewhere, but it is maintained that attention to these aspects has not solved the problem of ætiology.

FIG. 1 (Cat 77).

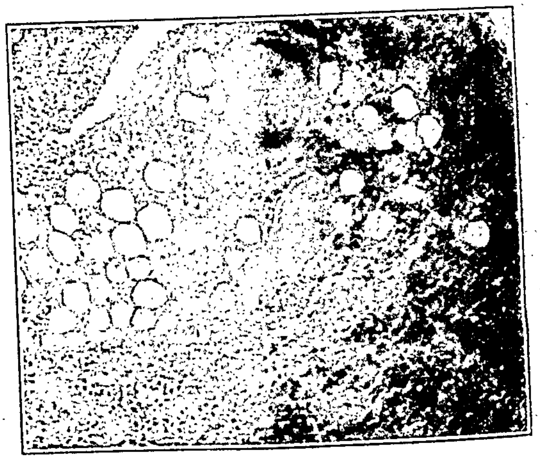


Section of ulcer formed after local injection of histamine. (× 20.)

Author's Experiments.

The cat was chosen for my experiments, as a plentiful supply was available; it can be fed in a more varied way than the larger rodents and, unlike those animals, it does not suffer from spontaneous peptic ulcer. The gastro-intestinal tract of the cat is large enough to permit of various surgical procedures, although, of course, greater delicacy is needed in such an operation as entero-anastomosis than in man or the larger animals. Certain special difficulties attended the course of the work, one of the most irksome being the liability of cats kept in confinement to die suddenly and without obvious cause. In these cases the most complete post-mortem failed to demonstrate any cause of death, and several cases were referred to a very competent pathologist with the same negative result. Much of the work was done under conditions of extreme heat, the shade temperature at times exceeding 110° F., so that post-mortem decomposition took place rapidly. Whenever possible, an immediate examination was made, but when circumstances forbade this the animal had to be discarded, as post-mortem changes obscured any pathology present; therefore, although the series included 80 cats, the number of effective experiments was rather less.

FIG. 2 (Cat 77).



Section of ulcer. (× 150.)

GENERAL TECHNIQUE.

The area of operation was shaved, washed with spirit-soap, and painted with iodine; instruments were boiled, except knives, scissors, and needles, which were kept in spirit, as was the linen thread, which was used for all sutures in the stomach, and also for closing the abdominal wound. During the operation the instruments were placed in 1/20 carbolic, and the operation field was surrounded by a carbolised towel. The abdominal wound was closed by two continuous sutures, one for the peritoneum and one for the skin, painted with iodine and collodion and left free of any dressing. The anæsthetic was ether by the open method.

This technique, and possibly the high resistance of the cat to sepsis, ensured healing of the abdominal wound by first intention in almost every case; the few exceptions were mainly among the group which were given histamine injections.

Only one complication ensued as a direct result of linen thread sutures, and that was a stitch abscess in the stomach wall of cat 65. The skin suture was usually extruded within a month, but at times remained in situ for as long as three months. The suture in the abdominal wall invariably persisted, as did the subserous sutures. Sutures between the mucous edges were gradually extruded, and this process was almost complete by the third month, and in certain cases much earlier.

The experiments included gastro-enterostomies—with occlusion of the pylorus and "en Y"—gastric transplantation of jejunal mucosa, and the production of ulcers by a ring, by section of the vagi, by adrenalectomy, and by subcutaneous and local injections of histamine. The last group will be described.

LOCAL INJECTION OF HISTAMINE INTO STOMACH WALL.

Attempts to produce a chronic type of lesion by subcutaneous injection having failed, it was decided to resort to local injection of the drug in the same way as Bolton used his gastrotoxic serum.

RESULTS.

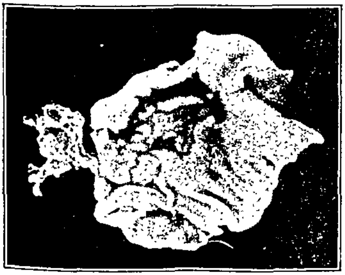
Cat.	Dosage in cg.	Method of injection.	Survival in days.	Course and post-mortem finding.
67	1	Local.	7	Cat remained well; site of injection normal.
68	1	Local*	7	„ „
76	2	Local†	6	„ „
77	3·5	Local†	6	Cat remained in good health and ate normally. Site of injection was occupied by raised hæmorrhagic area size of a halfpenny; surface resembled a ripe raspberry. Microscopical appearances described below and shown in Fig. 2.
78	3·5	Local†	39	Cat in poor condition for last 20 days of its life; continued to eat but in smaller amount with less avidity than usual; no hæmatemesis or melæna was observed. Site of injection was occupied by a large indurated ulcer, shown in Fig. 3. Adjoining ulcer was an elongated submucous hæmorrhage which shows well in photograph. The rest of the mucosa and all other organs normal.

* Thereafter similar subcutaneous dose daily.

† Thereafter one twice daily by subcutaneous route. Starvation on alternate days.

Technique.—The stomach was exposed and with a fine hypodermic needle 1 c.cm. of histamine solution was injected into the muscular layer of the stomach wall. The site chosen was on the lesser curvature near the pylorus, and to the right of it a control injection of sterile normal saline was given. The immediate reaction was rather more marked than in the case of subcutaneous injection, but recovery was rapid and there were no deaths in this series, all animals being killed by chloroform. After operation normal diet was allowed.

FIG. 3.



Ulcer formed after local injection of histamine. Note edge of ulcer and elongated submucous hæmorrhage.

Ulcers of Cats 77 *and* 78.—As these ulcers were the most remarkable finding in the series, they will be discussed in some detail. The ulcer of cat 77 shows an earlier stage of the same process as is seen in cat 78. Microscopically (Figs. 1 and 2) there is swelling of the mucosa accompanied by dilatation of the capillaries and small vessels, and an intense cellular reaction. (The fat cells seen in the upper part of Fig. 2 are probably an accidental inclusion.) It is clearly the separation of this turgid mucosa which has led to the ulcer seen in Fig. 3. On comparing the section with one taken from an acute ulcer resulting from subcutaneous injection of histamine, the main difference is the absence of cellular infiltration and capillary dilatation; the reaction is much less intense.

The ulcer of cat 78 (Fig. 3) resembles very closely a chronic ulcer as seen in man; there is a raised edge surrounding an irregular crater, the base of which is formed by the muscular coat. In the centre of the crater there is a small island of mucosa which has escaped destruction, and to one side there is an elongated submucous hæmorrhage which in the fresh state was a bright red streak. This hæmorrhage illustrates the process by which this type of lesion is produced, and had time permitted this area would have been included in the ulcer.

The only experimental ulcers which in any way resembled those just described were the gastrotoxic ulcers reported by Bolton. The main difference seems to be that in his ulcers the cellular and vascular reaction was much less intense but, as the plates in his book are the only present basis of comparison, it is difficult to make a very definite assertion. His gastrotoxic ulcers were a specific result of a specially prepared serum; this reproduction of a specific effect by a substance so protean in its origins as histamine is of more than passing interest.

The experiments which I have summarised show that it was possible to produce the various stages of acute ulcer by injections of histamine, and in this group an ulcer having the appearance of a chronic ulcer has been described.

The gastrotoxic ulcers healed, despite all efforts to delay that process; the fate of the solitary histamine ulcer will form the basis of further investigation.

Discussion.

The histamine ulcers, more especially the two of solitary type, were by far the most interesting lesions produced. Histamine is a product of protein disintegration and is produced by dead bacteria as well as by dead tissue; it seems to be a factor common to all the multitudinous methods which have been employed to produce ulcer experimentally and to the various processes which have been supposed to produce it clinically; it is a factor which links the simple injection of serum used by Bolton with the grossly mutilating surgical experiments of Mann; it is present in the cultures of streptococci employed by Rosenow; it is absorbed from the burnt surface of the skin; it is present in the various septic foci whose removal occupies so prominent a place in the present-day therapy of the disease. Whether in this view of histamine imagination has far outrun discretion, only the future can decide.

I am indebted to Major R. G. Archibald for giving me facilities to carry out this work; to him and to his staff for much valuable assistance and advice; and to Mr. O. F. H. Atkey, F.R.C.S., and the Council of the Durham University College of Medicine for permission to publish this paper.

IRRADIATION OF SCHOOL-CHILDREN.

By Sir Leonard Hill, M.B. Lond., F.R.S.,
DIRECTOR OF RESEARCH, LOND. LIGHT AND ELECT. CLINIC.

AND

Alan R. Laurie, M.B. Ed., D.M.R.E.,
M.O., ULTRA-VIOLET CLINICS, DERBY EDUCATION COMMITTEE.

A paper by Dr. Dora Colebrook on Irradiation and Health was published in the Special Report Series (No. 131) of the Medical Research Council in 1929. Based on the substance of her report, at the time unpublished, criticisms of light treatment appeared in the preface to the annual report of the Medical Research Council published earlier in that year. These criticisms excited much comment in the lay press, particularly so as light treatment had been used in the case of the King's illness, and apparently with success. Coming from such a source, the criticisms had an inhibiting effect on those who were considering the adoption or the extension of this method.

A NEGATIVE FINDING.

Dr. Colebrook having selected a school in which to investigate the effect of irradiation on the health and development of children, divided these into three groups, two of which were irradiated, the one by a naked arc lamp, the other by a lamp screened with window glass, while the third received no irradiation at all. Records were kept of height and weight, of incidence and duration of colds and allied conditions, of attack-rate of infectious diseases, of occurrence of chilblains, and of progress in school work. The results of irradiation were negative in all respects. In considering the striking discrepancy between these negative results and positive ones obtained by many medical officers at home and abroad, certain facts have to be borne in mind. First the school selected by Dr. Colebrook was not one in the slums of London, where the absence of light is greatest, but one in Willesden, where the conditions are good. Houses there are low-built, roads wide, the selected school modern, well-lit and having a large playground, and the district situated on the side of London where the westerly winds blow the smoke away, and ultraviolet readings are high, as shown by one of us (L. H.), using the acetone-blue gauge. Before any conclusions could justly be drawn such a school had to be contrasted with one situated in a poor district of central London. Secondly, Dr. Colebrook may have overdosed the children with powerful shorter ultra-violet rays. Those experienced in light treatment recognise the ill-effect of over-dosage. The children were irradiated from September to March on three days a week, with an interval at Christmas, and a powerful long-flame arc was used. A ten-minute exposure of 2 ft. 4 in. from the flame "gave a strong reaction with redness lasting for six days" in an adult. But the production of erythema cannot be used safely in children as a test of dosage; the children were put round the lamp at 2 ft. 2 in. from the flame, this being on a level with the middle of the child's trunk. The front and back body surfaces were irradiated on alternate sessions; circles were also painted on the floor at 2 ft. 6 in., 3 ft., and 3 ft. 6 in. from the lamp; the maximum dose was obtained with the children 2 ft. 2 in. away from the lamp for 15 minutes, the arc running on 70 volts and 30 ampères, the minimum dose with the children 3 ft. 6 in. away for five minutes, the arc running on 45 volts and 25 ampères. During the last part of the winter metal-cored carbons were used to intensify the dose. Mr. T. C. Angus measured the ultra-violet radiation of this arc lamp with the aid of a photo-electric cell, and found the strongest intensity to be about nine times that of a new Hanovia mercury-vapour lamp, which had settled down in action, while the weakest intensity used was nearly twice that of this mercury-vapour lamp.

RECORDED POSITIVE RESULTS.

At the Finsen Institute, Dr. Axel Reyn had insisted on the greater utility of the short-flamed arc, which gives relatively more infra-red and visible rays and less short ultra-violet rays. Long exposures are given by Dr. Reyn to such arcs and the patients made to redden and sweat with the heat; such exposure may be terminated by a cold shower bath. The statistics of this Institute show that results have been obtained by means of artificial light as good as those obtained by Rollier at Leysin by means of heliotherapy. Dr. Sequeira, no less, has obtained good results at the Light Clinic at the London Hospital, and Mr. W. S. Duke-Elder has reported very favourably on irradiation as a means of treatment of certain diseases of the eye. Good results had been obtained by Dr. Eidinow and one of us (L. H.) at the Light Clinic which they had got started in the New End Hospital, Hampstead, in which treatment was carried on by Dr. Madders as a voluntary worker. Favourable reports were received, too, by L. H. from several welfare clinics in which light treatment had been introduced on his suggestion. Dr. Murray Levick had obtained extraordinarily good results through irradiation of marasmic children. Favourable experience in regard to irradiation of children had been reported by Gamgee at Hull, Taylor and Griffiths at Aberdeen, and Banks at Motherwell—these among others. There were known, also, the good results of irradiation of animals at the Zoo which had been introduced in accordance with the advice of one of us (L. H.). By the introduction of open-air and artificial light treatment in the new monkey-house tuberculosis has been almost abolished. After completion of Dr. Colebrook's research, which gave negative results in the case of children living in good conditions and treated by short exposures to a powerful long-flamed arc, further research was then obviously indicated on children living under worse conditions and given light treatment with other intensities and times of exposure.

Such research was, therefore, initiated by us in the planning of which any personal bias was as far as possible eliminated by advice of statisticians. The results of this research are now given. The good results obtained by Huldschinsky, Hess and others, through irradiation of rickety children has been attributed to the formation of vitamin D in the skin, and it has been claimed that the giving of vitamin D by the mouth has all the good effect which irradiation has on children and offers a cheaper and easier means of treatment. It was decided to test this as well as the general efficacy of irradiation.

A Controlled Investigation in Derby.

Four areas of the town of Derby were selected—roughly, North, South, East, and West—and a random sample of 100 children were taken from each area. Four groups were formed, each group consisting of 25 children from each area, so that all groups were comparable as regards living conditions. The ages were between 9 and 12 years, and as the groups were formed by random sampling, any effect of age was minimised. The test extended over 16 weeks—from November, 1929, to March, 1930, with a break of a fortnight at Christmas.

Group 1 were given radiation 6 ft. away from a long flame tungsten-cored carbon arc twice weekly. The lamp ran on 85 volts and 15 ampères and the maximum dose was 10 minutes back and 10 minutes front 6 ft. away, about one-tenth of the maximal dose used by Dr. Colebrook, and this given twice, not thrice a week.

Group 2 were given one radiostol pellet at school daily. Each pellet has a dosage of vitamin D equivalent to that in about 2 oz. of a good cod-liver oil.

Group 3 were given exactly similar looking pellets but containing no radiated ergosterol daily, and attended, also for exposure to an arc fitted with a glass screen, twice weekly. This group was put in to demonstrate the part, if any, that psychology plays in the taking of pellets and the mere fact of undressing before a lamp.

Group 4 were controls, who had nothing done for them at all. The children were examined before the test, and the following points noted on the individual chart:—

1 Height and weight.
2. Hair abnormalities.
3. Skin abnormalities.
4. Conjunctivæ.
5. Temperament.
6. Eating.
7. Sleeping.
8. Tonsils and adenoids.
9. Cervical and submaxillary glands.
10. Evidence of gross disease—e.g., T.B. joints, rickets.
11. Liability to any particular disease.
12. Heart and lungs.

Six local practitioners took part in the examination—four of them took the heart and lungs, and two others the remainder. They conferred beforehand, to evolve a uniform method of recording. The treatments were then carried out and the children re-examined by the same doctors who had first examined them, but who were in complete ignorance of the groups to which the children belonged. The test was therefore secret, and the doctors could not be influenced in favour of any particular treatment. Unfortunately there was an epidemic of various infectious diseases in the town during the 16 weeks, which greatly curtailed our numbers, but the following results were based on 250 cases. No deductions were drawn from the following: hair, skin, heart and lung, and dental examinations (separate examination by school dental surgeons).

(a) *Weight.* Average gain in weight in lb. per child:—

Group 1	2·42	Group 3	1·81
„ 2	2·17	„ 4	1·91

(b) *Tonsil and gland group.*

Group.	Total.	
1	33	26 remain the same, 7 improve.
2	29	20 „ „ „ 3 „ 6 worse.
3	38	28 „ „ „ nil improve, 10 worse.
4	27	27 „ „ „

(c) *Percentage improvement in Groups 1 to 4.*

	(1)	(2)	(3)	(4)
Conjunctivæ	30	13	Nil	10
Eating and sleeping	57	45	17	7
Liability to winter complaints, colds, bronchitis	30	21	15	7

(d) Any *improvement on any chart* was marked with a plus, and the addition of these showed the groups to come out as follows:—

Group 1	162	Group 3	70
„ 2	130	„ 4	30

(e) *Percentage of children in each group who improved in any respect:*—

Group 1	80	Group 3	34
„ 2	47	„ 4	24

Conclusions.

Apart from these statistical results, the following deductions may fairly be made:—

1. That marked improvements under any particular heading, or class of headings, are always shown in Groups 1 and 2, and not by a small margin that could be due to fortuitous circumstances, but by a really appreciable margin.

2. That in no case do Groups 3 and 4 show better results than 1 and 2.

3. That Group 1 always shows slightly better results than Group 2.

4. That in *no* case, in Groups 1 and 2, was there any retrogression in the health of the children, except in the single instance of glands, for which there was an underlying cause, untreated except by irradiation.

5. The cases which made the really spectacular improvements were in Group 1.

6. The only instances of grateful thanks by parents were in Group 1 (spontaneous thanks noted).

7. The greatest effect on children seemed to be on their eating and sleeping.

8. The improvement has been most marked, in the case of the ultra-violet ray treatment, in the very headings we should most expect it, and slight, or absent, in the gland group, where there are such underlying causes as tonsils, bad teeth, and lice.

9. The period was too short to expect much change in temperament, but many parents reported the excellent effects of irradiation on nervy children, and that some children became naughtier.

Maugham and Smiley at Cornell University report that they have reduced the number of colds almost 60 per cent. among irradiated, cold-susceptible men as compared with the non-irradiated groups. Each man had 15 minutes total irradiation once a week, in an artificial "solarium" fitted with mercury-vapour lamps. There were about 300 receiving regular treatments. Successful results have been obtained by them during the last three winters. In America such "solaria" have been put up in factories. If even half the relief claimed to be given to these university students could have been given to the population at large, what an immense saving would have been effected.

We are indebted to the authorities, the school medical staff, and the local practitioners who took part in the Derby scheme and helped to make this research possible.

MELANOMA FOLLOWING "CRAB-YAWS."

By Clement C. Chesterman, O.B.E., M.D., M.R.C.P. Lond.,
PHYSICIAN IN CHARGE, YAKUSU HOSPITAL, BELGIAN CONGO.

During the ten years 1921–30 eight cases of malignant disease have been diagnosed among Bantus of various tribes at the hospital of the Baptist Missionary Society at Yakusu, near Stanleyville in Belgian Congo, and three of these (37 per cent.) were cases of melanoma arising from the skin of the sole in adult males. The total number of cases seen during the period was about 40,000 and it is noteworthy that only eight cases of malignant tumour were diagnosed (or 1 in 5000 of the total in- and out-patients), and that these included as many as three melanomas of similar origin.

Case 1.—Asisa, aged 35, had an ulcerated tumour, the size of a golf ball on his left heel. He had suffered from "crab-yaws" at this site for many years. There were small glands in the groin. The tumour was amputated and was almost wholly black on section. The patient was lost sight of.

Pathological report (by the kindness of Dr. H. B. Newham of the London School of Hygiene and Tropical Medicine) confirmed the clinical diagnosis of "melanotic sarcoma" of low malignancy with a considerable degree of fibrosis.

Case 2.—Ilenge, aged 43, had an ulcerated tumour the size of a tangerine orange in the middle of the sole of the left foot, which had been the site for some years of crab-yaws. Large crural glands were found. The patient was weak and emaciated. The tumour was amputated and was uniformly black on section. A month later the crural glands broke down and a black discharge exuded from two or three sinuses. The patient died from exhaustion and secondary deposits in lungs and liver.

CASE 3.—Liusola, aged 45, had an ulcerated tumour the size of a cricket ball growing from the ball of the right foot, which had previously been affected by crab-yaws for many years. The tumour had first been noticed 18 months previously. Large hard crural glands were found. The tumour was amputated, with a wide clearance of all surrounding skin, which showed a thickened pigmented layer. About 12 black glands, varying in size from a pea to a pigeon's egg, were removed by wide dissection round the femoral vessels. Two months later the foot wound had cicatrised and the patient had gained 5 kg. in weight.

Three cases of undoubted melanoma of low malignancy occurring in adult males, arising from the skin of the sole (which is normally no more pigmented in negroes than in Caucasian stock), seem of special interest in that they appear to have a common carcinogenic factor in the prolonged irritation due to crab-yaws. This is a chronic granulomatous condition beneath the skin of the sole or palm which may appear some years after the generalised secondary eruption of yaws and, owing to the thickness of the epidermis, tends to persist as an open fissure or ulcer. It seems therefore that the *Treponema pertenue* of yaws must be regarded, like its congener *T. pallidum* of syphilis, as a potential carcinogenic agent, producing as it does chronic fibrosis and hyperkeratosis.

In searching for any other possible factor in these cases I learnt that a native remedy enjoying a great vogue is the holding of the foot affected with crab-yaws in the hot smoky flame produced by burning some powdered resin, of a type commonly used as an illuminant, in a little hole in the ground. The soot from this burning resin is deposited in the ulcer and a hard coagulum is formed, which apparently is successful, not infrequently, in promoting healing. Occasionally the thickened skin is scared by the flat blade of a knife heated in the fire. The third patient admitted on interrogation that he had resorted to this practice just before the development of the tumour, and subsequent investigation leaves me with very little doubt that the other two cases had made use once, if not more often, of this popular remedy. Bearing in mind the well-known carcinogenic properties of soot, tar, paraffin, and mineral oils, it is not impossible that this practice may be a contributory factor. Most native medicines for external application contain charcoal and palm oil, and these, with an abundant supply of ultra-violet light, may also exert some influence in the development of malignancy.

References in such literature of cancer among negroes as is available to me lend support to the hypothesis of a relationship between melanoma and crab-yaws. Connor[1] (1929) states that, in hi experience in Bengal, melanotic sarcoma is commone than in Europe, and illustrates a case arising fro the palm which is practically identical in appearanc with the cases here reported from the sole. He doe not refer to yaws, although this disease exists i eastern Bengal. Watkins-Pitchford[2] (1923) note that the natives of Natal are especially liable t "sarcoma of the subcutaneous tissues of the foot." In the précis of his paper it is not clear whether h refers to melanoma or not, nor is crab-yaws mentioned as a possible factor, although yaws is endemi in Natal. Adler and Cummings[3] (1924) record case of melanotic sarcoma in the foot of a Wes African negro.

CLINICAL AND LABORATORY NOTES

INSULIN PHOSPHOTUNGSTATE BY MOUTH.

BY R. D. LAWRENCE, M.D. ABERD., M.R.C.P. LOND.,
CHEMICAL PATHOLOGIST, KING'S COLLEGE HOSPITAL (IN CHARGE OF DIABETIC CLINIC).

IT has recently been reported by Mukherjee[1] that a compound of insulin and phosphotungstic acid is active when taken by mouth. The positive evidence was obtained by the production of hypoglycæmia in normal rabbits and diabetic patients. More recently O. Leyton has reported to the Royal Society of Medicine encouraging results on diabetics. My investigations have not been encouraging and fail to demonstrate that this compound of insulin has any action when taken by mouth.

The substance was tried in large doses on two "pedigree" insulin cases of moderate severity and the results are definitely negative.

Case 1.

	8 A.M.	9 A.M.	11 A.M.	Noon.
Blood-sugar per cent.	0·23— 24 units ..	Breakfast ..	0·154 ..	0·114
	0·25—100 „ .. tungstate.	„ ..	0·436 ..	0·468

Case 2.

	1 P.M.		5 P.M.
Blood-sugar per cent.	0·084— 0 units	.. ..	0·190
	0·123— 5 units	.. ..	0·098
	0·132—100 „	tungstate ..	0·222

Case 1 requires 24 units of insulin injected one hou before a standard breakfast to reduce the bloo sugar to normal at noon. 100 units of insuli tungstate were given by mouth one hour before similar breakfast and did not prevent extreme hype glycæmia. This was accompanied by thirst, polyuri and a heavy excretion of sugar (5·3 per cent.) an ketone bodies.

Case 2 was investigated differently. As th figures show, his blood-sugar rises after lunch in th afternoon when the action of his morning insuli wears off. Five units of insulin injected check this afternoon hyperglycæmia, but 100 units of th tungstate compound by mouth showed no suggestio of insulin action.

These doses were very large in comparison wit the usual amount of injected insulin and therefor the compound seems of no practical value. It ha been known for years that very large doses of insuli administered by mouth in alcoholic[2] solution o with saponin[3] may occasionally have some sligh hypoglycæmic action on the blood-sugar of animal and diabetics. But this action is variable an uncertain and depends on the absorption of som insulin before it is destroyed by the digestive enzymes a factor over which we have no control. Phosphotungstate insulin seems no better than othe forms of insulin by mouth, as might be expected. The chemical nature of the compound, also, would make one fear a toxic action on the kidneys.

TREATMENT OF SUPERFICIAL SEPTIC INFECTIONS BY NASCENT IODINE.

By W. E. Waller, M.D. Oxf., M.R.C.P. Lond.

Superficial septic infections of the fingers and hands frequently pursue a chronic course and are most troublesome to treat. One of the most obstinate of these conditions starts as a purulent blister, usually near the tip of a finger or thumb. This is opened, the dead overlying epidermis is cut away, and with simple antiseptic dressings the condition may clear up rapidly. Very frequently, however, the infection "creeps" under the epidermis, raising it as secondary purulent blisters at the margin of the primary one, and this process, once started, shows a strong tendency to extend to and infect the nail-fold. Once established here, it may persist as a mild septic onychia for many weeks, causing prolonged disability. Sometimes the process appears to heal, only to reappear again shortly as beads of pus under the nail-fold. If the nail-fold is cut away together with the nail base, if pus has travelled beneath it, healing occurs forthwith, but such a procedure renders necessary some form of anæsthetic, and since the local injection of novocain round the base of the finger or thumb, though entirely effective, is not without risk in the neighbourhood of such sepsis, a general anæsthetic is required. These procedures are usually resented by the patient, who does not understand why so apparently simple a condition cannot be cured by simple methods.

For some years I have used the following line of treatment in these cases, the effectiveness of the method being apparently associated with the liberation of free iodine.

1. Soak the part for five minutes in hydrogen peroxide, 10 volumes per cent.
2. Transfer for five minutes to mercuric potassium iodide, 1 in 2000 solution. This solution becomes brown from liberation of iodine.
3. Dress with gauze wrung out of the biniodide solution, cover thinly with cotton-wool, but use no waterproof protective. These procedures are carried out twice daily.
4. Change to dry dressing and omit all dressings at the earliest moment.

If the nail-fold is a deep one, it may be necessary to raise it with an eye spud or similar instrument, and insert small pieces of sterilised rubber tissue to assist drainage. Most cases clear up readily by this method, which is simple and cheap. In my experience boric compresses or fomentations or flavine or other antiseptic compresses frequently fail or appear to do positive harm, but since adopting the method outlined above I have rarely had to resort to operation, unless there is already pus under the nail when the case is first seen.

Similar superficial septic conditions, not involving the nails, have cleared up under this treatment when other methods have failed.

Rustington, Sussex.

MEDICAL SOCIETIES

BRITISH INSTITUTE OF RADIOLOGY.

At a meeting of this Institute on Jan. 15th, Major C. E. S. Phillips, the President, took the chair, and a paper on

Hydatid Disease in England

was read by Dr. J. F. Brailsford (Birmingham). He explained that the chief reason for his communication was the oft-recurring statement by both physicians and surgeons that hydatid disease was rare in this country—a statement with which he now disagreed. He was reading the paper before the Institute rather than a purely medical society because radiologists came more frequently in contact with hydatid disease than anyone else; most of the recorded cases had been seen, at some stage, by a radiologist. Though the disease was not rare in this country, it was much more common in large sheep-breeding areas, such as Iceland, Australia, and the Argentine. The danger lay in animals. For several years he had paid daily visits to the Birmingham public abattoir, and saw many cattle, sheep, and pigs infected with the parasite (*Tænia echinococcus*). Some herds were extensively infested with it, others very little. In most of the cases the cysts were multiple, almost completely destroying the normal tissue, the livers of some of the infected cows weighing as much as 200 lb. instead of the normal 14 lb.

Cases of human infestation were occasionally to be seen in hospital, and there was a great variety of clinical signs arising from the presence of the parasite; this might account for the fact that some 300 articles had appeared on the subject in the last five years. Yet the persistence of cases showed that no concerted effort had been made to eradicate what was a formidable disease, and one which could be as surely banished as rabies had been. In a large number of instances, the prohibition by councils of dogs at abattoirs was not kept, dogs being allowed to enter and consume offal which was very likely to include parasites in some stage, such dogs easily passing along the infection to a human being, especially if much fondled. Slaughter-house refuse was sometimes used for manure, in which the tænia flourished. Foxes were very prone to the disease; a young woman subject had a pet fox, which she taught to receive sugar from between her lips, by which means no doubt she derived the disease. It had been found in the wolf, the jaguar, and other animals of the kind, and he believed that a proportion of sheep-dogs harboured the echinococcus. In Australia active measures had been directed against these dogs, and since they were started the number infested had been showing a diminution. In this country, so far, no concerted action had been organised against this serious disease. He wrote to the Ministry of Agriculture and Fisheries to ascertain what leaflets or pamphlets had been issued on the subject, and their only reply was to refer to a leaflet on sturdy, which, of course, was a different disease.

A very important point was that hydatid disease might exist in a person for as long as ten years before it was suspected; hence it was difficult to date the origin of a case, or to trace the source of contamination. Ordinary house-flies could deposit the worm on food. The echinococcus measured about one-was to treat the disease and leave the pregnancy alone.

Mr. L. Carnac Rivett regarded the combination of tuberculosis and pregnancy as a serious thing. Ernest Ward had published particulars of 423 pregnancies in 237 tuberculous women. In 53 per cent. the pregnancy had no effect on the disease; in 16 per cent. the lesion was improved, in 31 per cent. the tuberculous lesion was rendered worse by the pregnancy. In another series of 422 labours, there was no effect from the pregnancy in 32 per cent., the tubercle was improved in 19 per cent., while in 49 per cent. it was made worse. In 1925 Dame Louise McIlroy read a paper before the Section giving the results in 18 tuberculous cases at the Royal Free Hospital, in which she cast the onus—as the speaker would—on the physicians, as there was so little coöperation between maternity hospitals and sanatoriums, and cases were sent out of sanatoriums before labour became due. Mr. Rivett would go further and say that many patients were discharged from sanatoriums because they were discovered to be pregnant. Dr. R. A. Young had declared that pregnancy was bad for tuberculous lesions, remarking that a lesion was often latent or quiescent during pregnancy, flaring up after delivery. He had expressed himself thus: If a virgin, no marriage; if married, no pregnancy; if pregnant, no confinement; for the mother, no suckling. Morris and Murphy had published 166 cases which were followed up for three months after the termination of pregnancy; in 37 per cent. there was no change, in 18 per cent. there was improvement, in 39 per cent. the patient was worse, and 6 per cent. died. In the presence of active tuberculosis abortion must be practised for the sake of both mother and child. Any woman who was pregnant and had an active tuberculous lesion should receive full sanatorium treatment during the whole of her pregnancy, and for at least six months afterwards. Turning to the effect of the tuberculous lesion on the pregnancy, this was usually uneventful; tuberculosis showed no particular tendency to cause abortion. The child was usually on the small side, 6¼ lb. on the average, and there was no reason to interfere with the labour, especially as anæsthetics were inadvisable. There was no tendency in these cases to post-partum hæmorrhage, or sepsis, or subinvolution. For the tuberculous mother he advocated no suckling. He hoped that, as a sequel of this discussion, the Ministry of Health would be urged to make proper provision for these cases.

DISCUSSION.

Dr. Jane Walker said that in an inquiry she made in 1926 the general trend of opinion was against the termination of pregnancy in tuberculous women; indeed there was practical agreement as to the uselessness, even the danger, of bringing on labour in the later stages. At a discussion in Cambridge the general opinion was that if pregnancy was to be terminated, it should be done by Cæsarean section, an operation which could be performed quickly and with little danger. In only one case of her own was it considered desirable to terminate pregnancy, and that was between the fifth and sixth month. A successful artificial pneumothorax had been induced, and the patient was doing well, but it was felt that the strain of parturition might be prejudicial. She died soon afterwards. As to lactation, to her surprise all the replies were against allowing the mother to nurse her baby; whereas her own view was that it was an advantage to both mother and child that the latter should be suckled by her. As to the treatment of a tuberculous woman during gestation, most of the correspondents thought the pregnant woman should be treated in the same way as *if she were not pregnant*, and with that she agreed. In acute active phthisis, pregnancy was a calamity, and its termination, at any period up to the tenth week, should be entertained. In cases of arrested phthisis, pregnancy had no ill-effect, but the period of lactation should be carefully supervised. The London County Council had under consideration, after consultation with Dame Louise McIlroy and herself, a scheme for tuberculous women to be sent to a sanatorium for confinement and the ensuing six months. But it was found that women objected to going.

Dr. J. S. Fairbairn said he was only prepared with a few impressions. It was only in the early or the recently cured cases of phthisis that termination of the pregnancy arose. He doubted whether it was sound to depend on the advice of physicians, as many of them seemed to regard pregnancy almost as a sort of malignant growth. He admitted, however, that a number of tuberculous women had an exacerbation of the disease after delivery.

Dr. Margaret Salmond analysed some figures from the Royal Free Hospital where a considerable number of tuberculous cases, mostly from Brompton or Grove Park, were admitted for confinement and sent back afterwards. It was, she said, not advisable to put active tuberculous cases in a ward with normal mothers and babies. The ideal would be to have a small antenatal ward, labour ward, and lying-in ward and nursery for tuberculous patients. It had been found that after 16 weeks, if the disease was active, there was but little point in inducing abortion, as the disease was usually aggravated as much by this procedure as if the patient were allowed to proceed to term. For the prevention of future pregnancy, where it was considered undesirable, contraceptive advice was given; but in patients of the hospital class this was rarely carried out satisfactorily. Sterilisation in young patients by X rays and radium had the disadvantage of producing an early artificial menopause, which was undesirable. The babies born of tuberculous mothers were all of good average size, and seemed healthy. Many patients with active disease were sent to sanatoriums after delivery, and the baby was sent home to friends or relatives until the mother improved.

Dr. S. Vere Pearson said that tuberculous patients who were pregnant did well under sanatorium treatment. The mothers themselves objected to being confined in a sanatorium; sanatorium physicians did not object, provided they could find a quiet room apart so that other patients were not disturbed by a child's cries.

Dr. Eric Webb called attention to the energy involved in bringing a child into the world, and the fact that a quick induction of labour caused more reaction and shock than a slow one. There was also a good deal of energy entailed in lactation.

Dr. F. H. Young gave the meeting some particulars of pregnant cases in an artificial pneumothorax clinic. In the past 4½ years he had had 120 women undergoing artificial pneumothorax, chiefly at Brompton Hospital. Eight had become pregnant. In five the pregnancy was detected early and was terminated. In three it was detected late and was allowed to go on. In none of the eight cases did the tuberculosis seem worse after the pregnancy, and he had the opportunity of following them *for six months afterwards*. He induced artificial pneumothorax in three patients who were discovered to have phthisis during their pregnancy, and all of them went through the labour successfully and were no worse afterwards.

Dr. R. A. GIBBONS did not agree with sterilisation of these patients, as there was always the hope that sanatorium treatment would get them well. He favoured leaving to the physician the decision as to what should be done.

Prof. LYLE CUMMINS said the tuberculosis officer often had the question put to him "Should this young woman get married?" He exhibited a table showing that in a large number of cases the health of married women was superior to that of single, divorced, or widowed women, probably because of the shelter of a home and the absence of the need for participating in the struggle for subsistence. In the case of the mother acutely ill with tuberculosis it would of course be criminal to allow lactation. Where the disease was in a condition of arrest, the risk was not worth thinking about. It should be borne in mind that children were more easily infected with tubercle than were adults.

HUNTERIAN SOCIETY.

AT a meeting of this Society on Jan. 19th the chair was taken by Prof. A. W. SHEEN, and a paper on the

Problem of Rejuvenation

was read by Dr. ARNOLD LORAND, of Carlsbad. He said that he had often observed the early appearance of symptoms of old age in people suffering from a lack of hydrochloric acid in the stomach together with an underfunctioning of the thyroid gland and an anæmia. Achlorhydria was known to be associated with myxœdema and with degenerated conditions of the pituitary gland. Anæmia was also well known to be associated with old age and with achylia. The anæmia of old age might be the direct result of thyroid degeneration or of the intestinal auto-intoxication which so frequently followed achylia. The relationship between lack of hydrochloric acid, intestinal auto-intoxication, and cancer had frequently been discussed, but endocrine changes might also play a rôle in the production of cancer. In the few cases where cancer had appeared in young people it had been accompanied by premature old age with achylia and anæmia. Achylia, especially in the aged, meant intestinal intoxication, and both together meant anæmia. All these contributed powerfully to the production of premature old age. Toxic products from the intestines had much to do with the development of high blood pressure and arterio-sclerosis. Old age could be considered as a condition of general auto-intoxication with resulting anæmia and inadequate nourishment of tissues.

The slogan of treatment must be: more blood to the tissues, blood containing all the necessary elements including the hormones and salts. The improved blood-supply must be accompanied by dietetic and drug treatment for the prevention of intestinal auto-intoxication, together with ultra-violet rays to stimulate the endocrine glands and the peripheral circulation. Rejuvenation could be accomplished by these means and especially by a wise selection of diet. Many foods had therapeutic properties superior to those of drugs; according to Carl Haug, spinach was a greater stimulant of hydrochloric acid than coffee and came next to histamine. Foods deleterious to the endocrine glands, and especially to the liver, must be avoided. The worst of these were meat and fats; of all protein substances, meat caused most putrefaction and casein least. If fats were to be used, preference must be given to those which melted most easily. Fat meat arriving in the colon insufficiently digested would stagnate there. The best fats were butter—which actually prevented putrefaction—and fine olive oil. The liver acted best when well stored with glycogen; potatoes, steamed rice, bananas, and sweet fruits were the best source of starch. Starchy food was an active agent against putrefaction, especially if sufficient milk were taken with it. The best milk products were sour milk, yogurth, and acidophilous milk; fresh cottage cheese was also good.

In the general interests of longevity the best diet was milk products, brown bread, vegetables, and fruit, with the addition of a few eggs and fish and only a little meat. Such a diet prevented constipation, and strong cathartics should be avoided. The bowels should be cleared out before treatment was instituted and one of the best methods was the "enterocleaner bath." Food should be daintily cooked and tasty but free from sharp sauces and spices, which were the villainous associates of an incapable cook and a greedy inn-keeper. Badly cooked food was badly digested and might be rejected unused and even contribute to the inadequate utilisation of the better cooked and more valuable parts of the diet. Good cooking ought to be taught in all schools. Coffee did not merit the calumnies levied against it; it might be good for the heart and its blood pressure-raising and uric acid-forming actions had been much over-rated. The wise physician should not be alarmed at a high blood pressure in old age. Transplanted glands were of very doubtful viability and there was no need to transplant a thyroid when it could be given by the mouth. Dr. Lorand had seen a spinster of 48 treated by thyroid and ovarian preparations, iron and arsenic, radio-active mud baths, and ultra-violet rays; menstruation had continued until her 53rd year, and she had looked considerably younger than her age. The best surgical method was the chemical sympathicectomia of Doppler, but even this had only temporary effects. Many grafting operations were undertaken solely to restore sexual efficiency; this procedure was fallacious and based on unjustifiable analogies between rats and man. Impotence was not a normal attribute of old age; it was a disease of the imagination at any age and could be as effectively treated by diet as by operation. The way of rejuvenation undoubtedly lay through the stomach and intestines; as Seneca had observed, more people were killed by the stomach than by the sword. Old age could not be transformed into youth, but youth and the duration of life could be prolonged. It was quite possible to make a man of 65 look 55. The best treatment for old age was its prevention.

DISCUSSION.

Prof. W. E. DIXON said that he was disappointed in being advised to eat olive oil and beetroot—which he loathed—instead of taking some simple internal secretion. Our diet was prescribed by tradition and not by a vicious appetite. He preferred to remain aged than to be rejuvenated by olive oil.

Mr. W. IBBOTSON inquired whether alcohol and tobacco were concerned in old age.

Dr. W. S. C. COPEMAN remarked that both the primary anæmias were known in this country as diseases of early middle age, and suggested that the syndrome mentioned by Dr. Lorand was probably different from the pernicious anæmia of the English

Eagles and D. McClean (London). Subcultures have been carried through seven generations with satisfactory evidence of multiplication in a medium composed of fresh kidney extract, serum, and Tyrode's solution.—Alum-toxoid Precipitates as Antigens, by A. T. Glenny and Mollie Barr (Beckenham). The precipitate formed by adding potash alum to formalised diphtheria toxin is a very effective antigen, apparently because of its slow absorption.—Observations on the Rôle of the Spleen in Antibody Production, by R. W. Scarff (London). The effect of splenectomy depends on the rapidity with which the spleen takes up and dissolves the various antigenic particles.—Extensive Subpial Hæmorrhage Due to Detachment of the Anterior and Middle Cerebral Arteries from the Anterior Perforated Spot, by W. J. Logie and P. M. Baird (Falkirk). Caused by a double punch on the head which did not injure soft tissues or skull.—Elementary Bodies in Various Virus Infections, by J. C. G. Ledingham (London). Minute bodies about 0·25µ in diameter are found in several virus diseases—vaccinia, fowl pox, psittacosis, ectromelia. The "inclusion bodies" consist of agglomerations of these "elementary bodies."—The Lining of Abscess Products in Dermis by Epithelium, by J. C. G. Ledingham (London). Cutaneous abscess cavities acquire a lining of epidermis by extension from the skin.—The Intravitam Staining of Bone with Madder and other Plants, by G. R. Cameron (London). Feeding rats with the roots of lady's bedstraw and other members of the natural order Rubiaceæ stains their bones red as with madder.—A Patent Ductus Arteriosus in an Aged Horse, by T. Hare (London).

British Journal of Children's Diseases.

IN the issue for October–December, 1930 (Vol. XXVII.), Dr. T. F. McNair Scott contributes a paper on Post-Vaccinal Encephalitis in Infancy in which he records a personal case in a male infant of 6 months who recovered without special treatment, as well as 21 cases collected from the literature of post-vaccinal encephalitis in the first year of life, emphasising the extreme rarity of the condition at this age compared with other periods of life. Five clinical forms are described—namely, meningitic, cortical, tetaniform, brain stem, and lower motor neuron types—of which the meningitic is the commonest. Of the 22 cases 12 died, but only one of the survivors showed any sequelæ.—In An Analysis of One Hundred Cases of Failure of Breast Feeding, Dr. H. W. Pooler, medical officer to the Child Welfare Centres of the Derbyshire County Council, comes to the conclusion that return to domestic duties is the principal cause, accounting for 63 per cent. of the failures. Too frequent feeding was only a subsidiary cause, while nipple trouble, the importance of which does not appear to be sufficiently emphasised in antenatal instruction, accounted for nearly one-quarter of the whole number of cases.—In their Study of the Specificity of the Hæmolytic Streptococcus Associated with Scarlet Fever, Dr. T. Toyoda, Dr. J. Moriwaki, Dr. Y. Futagi, and Dr. S. Hoshizaki, of the Japanese Government Isolation Hospital, Dairen, Manchuria, bring forward evidence to prove that neither morphologically, biologically, nor serologically can scarlet fever streptococci be regarded as possessing a specificity differentiating them from other hæmolytic streptococci.—Dr. E. H. R. Harries and Dr. E. C. Benn report two cases of Sublingual Mumps with Œdema of the Tongue in a boy aged 8 and a girl aged 13 respectively. No previous example of this complication appears to have been recorded.—Dr. James Wright publishes a case of Pyonephrosis as a Complication of Typhoid Fever in a boy aged 11. The typhoid bacillus was isolated from the urine and from the pus of the pyonephrosis. Death took place a fortnight after the operation. The patient had had no previous renal trouble, and no renal symptoms had occurred during the course of typhoid fever.—This issue contains a remarkably full index which will form a useful guide to current pædiatric literature.

REPORTS AND ANALYSES

DU MAURIER VIRGINIA FILTER-TIPPED CIGARETTES.

(PETER JACKSON (TOBACCO MANUFACTURER), LTD., 217, PICCADILLY, LONDON, W.1.)

AT one end of these cigarettes there is attached a filter-tip covered with cork. The filter, which is 1·2 cm. long, is composed of three layers of white vegetable tissue resembling crepe paper, with alternate layers of fine cellulose, each of these layers being about 6 cm. long. When rolled together a light compact mass results, which acts as a filter to certain of the undesirable constituents of tobacco smoke without producing any "drag" in the suction. No central cavity remains through which a straight stream of smoke could impinge on the tongue. The filter-tip is partly selective in its action and retains pyridine bases and non-volatile bodies which are generally held to be the principal cause of throat irritation.

Additional advantages of the filter-tip comprise protection of the lips, teeth, and fingers from unsightly stain, and prevention of fragments of tobacco from getting into the mouth. The smoke is cool and sweet, and no tobacco is wasted as in the ordinary cigarette end. The average weight of each cigarette is 1·31 g. (22 to the ounce), of which amount 83·5 per cent. is tobacco.

When analysed the following results were obtained on the tobacco:—

Moisture	13·4	per cent.
Ash	9·77	" "
Oil (petroleum ether extract) ..	3·17	" "

The percentage of oil is well below the customary limit, and the tobacco itself is of a high-grade quality.

We have tested these cigarettes and find them to be cooler and less irritating to the mucous membrane than ordinary cigarettes of good quality without the filter-tips. The Du Maurier cigarettes may be regarded in every way as satisfactory, and they constitute a distinct and hygienic advance in the marketing of cigarettes.

BANTAM COFFEE.

(THE BANTAM PRODUCTS LTD., LEEDS.)

This is a dried coffee extract, and when analysed the following results were obtained:—

Moisture	2·24	per cent.
Ash	13·88	" "
Soluble in petroleum ether ..	0·26	" "

The preparation dissolves completely and with ease in hot water, and the flavour is pleasant and very closely resembles that of coffee prepared in the ordinary way for domestic use.

It will be noted that the amount of matter soluble in petroleum ether (mostly oil) is so small as to be negligible, whereas, in the roasted coffee bean this figure averages about 14 per cent., and the bulk of it would find its way into the cup. It is likely that the absence of oil in this extract renders it more easily digestible than ordinary coffee.

This extract should prove acceptable for a variety of purposes, as it is so easily and quickly prepared by the addition of hot water, and, moreover, is free from any "grounds." It is claimed to be the equivalent of ten times its weight of ordinary roasted coffee.

THE LANCET.

LONDON: SATURDAY, JANUARY 24, 1931.

MYOMECTOMY.

IN 1843 the first abdominal hysterectomy for uterine fibroids was performed by A. M. HEATH, who duly recorded the event in the *London Medical Gazette* of that year. The patient unfortunately died from hæmorrhage 17 hours after the operation. Other attempts to remove the uterus were made by CHARLES CLAY of Manchester in 1844, and by JOHN BELLINGER in 1846, but their efforts were attended by no greater success, and it was not until 1853 that the first recovery after total abdominal hysterectomy was published by WALTER BURNHAM in Nelson's *North American Lancet*. Compared with ovariotomy, first performed by MACDOWELL in 1809, intraperitoneal operations upon the uterus are therefore a comparatively modern development of abdominal surgery. The last 50 years have, however, witnessed steady and sustained progress in the art of surgery, and in the realm of intraperitoneal technique pelvic surgery has worthily occupied a premier and in certain respects a pioneer position. Conservatism and the restoration and maintenance of physiological function is or should be the ultimate goal of surgical treatment. Hysterectomy, however perfectly it may be performed, is in the nature of things a mutilating procedure, resulting in a varying degree in functional disability according to the age of the individual upon whom the operation is performed. It is therefore perhaps a matter for some surprise that gynæcological surgeons, whilst perfecting the art and technique of hysterectomy to the degree of excellence which is possible to-day, have in the past somewhat neglected the conservative operation of myomectomy. From the broad standpoint myomectomy is indeed as old or an older operation than hysterectomy, for the early pioneers of ovariotomy have recorded the removal of large abdominal tumours of uterine origin by clamping and division of the pedicle. The ablation of a pedunculated subperitoneal growth is, however, a very different procedure from the enucleation of one or more fibroid tumours embedded in the wall of the uterus. This was carried out successfuly in 1897–98 by W. ALEXANDER of Liverpool, who removed 25 neoplasms and conserved the uterus. ALEXANDER's successful technique published in the *Medical Press and Circular* and *British Gynæcological Journal* does not appear to have attracted the attention it undoubtedly deserved, and apart from a few isolated records the literature on the subject is remarkably sterile. This was undoubtedly due to the surgical popularity which naturally attended the development of the easy and safe technique of subtotal hysterectomy. Indeed, myomectomy was relegated to the position of an operation of opportunity rather than a method of election. Recent work appears to indicate the need for a careful revision of this attitude of mind. In the light of modern surgical technique can myomectomy offer anything which hysterectomy, total or subtotal, cannot, and if so at no greater risk? Mr. VICTOR BONNEY, in a Hunterian lecture which we publish in our present issue, makes a strong claim for the thesis that myomectomy should now supersede hysterectomy as the operation of choice when uterine fibroids require surgical intervention. His view is based upon the results of 403 myomectomies performed by him from 1910 up to the present day. In 166 cases the tumours were solitary fibroids; in 237 they were multiple. In the latter group some remarkable figures are given relating to the actual number of tumours removed. In one instance as many as 125 fibroids were enucleated from a single uterus and apparently numbers from 15 upwards are by no means uncommon.

The first criterion of the value of any operation must always be the question of mortality. There is no doubt that in the past one of the main reasons which militated against the more general adoption of myomectomy was its higher mortality when compared with subtotal hysterectomy in the same type of case. In the earlier operations this was undoubtedly high, mainly as the result of hæmorrhage and sepsis. In Mr. BONNEY's series the operative death-rate was 1·7 per cent., a figure which compares entirely favourably with the same mortality attached to hysterectomy for fibroids to-day by gynæcological surgeons as a group. Comparing the operative risk of the two operations, it must be remembered that the myomectomy figures are those of an exponent of the highest surgical skill and that probably the majority of the operations were performed in the midst of surroundings replete with every facility which modern science can devise. As the result of the stimulus given to myomectomy by BONNEY's and LEITH MURRAY's lead it is probable, however, that other surgeons will be drawn to the same field. It is to be hoped that they will publish their successes and failures with the same frankness in order that the true value of the operation may be truly assessed. Improvement in the technique of the actual operation has contributed very considerably to the reduction in the initial mortality from hæmorrhage. The control of all bleeding by means of a special myomectomy clamp which embraces the round ligaments and supravaginal cervix is undoubtedly a valuable adjunct. The employment of a single primary incision preferably through the anterior uterine wall with subsidiary secondary incisions in the substance of the organ giving access to the individual tumours is also a technical advance by eliminating the troublesome intraperitoneal oozing so commonly a feature associated with multiple cuts through the uterine tissues. The planning of the incision to avoid scars at the uterine fundus and on the posterior wall prevents the adhesion of small intestine with the risk of intestinal obstruction. It is interesting to note that Mr. BONNEY has no compunction in opening the uterine cavity and incising the posterior uterine wall to enucleate a fibromyoma in this situation in order to avoid the necessity of a separate peritoneal incision. Indeed, exploration of the uterine cavity is advocated in many instances with the object of removing redundant hypertrophic endometrium and if necessary reducing the area of the menstruating surface. The nature of the actual operation, adequate for an individual case, naturally varies with the anatomical location of the tumours present. For large tumours in the posterior uterine wall too large for "transcavity enucleation" Mr. BONNEY has devised an ingenious procedure which he aptly terms the "hood operation." The technique necessarily involves considerable mutilation of the uterus, and it would be interesting to have figures of the after-history of patients upon whom this operation has been performed, as distinct from the main bulk of myomectomy statistics. In the performance of myomectomy involving the enucleation of numerous tumours the observance of a rigid aseptic ritual is second only in importance to the control of hæmorrhage. Much suture material is necessarily buried in the uterine wall and therefore the catgut employed must be irreproachable, in which connexion a tribute is paid to the Chorda catgut of Prof. W. BULLOCH.

After mortality the value of any operation can only be judged by reference to the subsequent health and happiness of the individual and to the function of the organ primarily involved. With regard to myomectomy it has been argued that the enucleation of many fibroids from the uterine wall leaves a scarred and damaged organ which is liable to develop more neoplasms, which is still a source of discomfort to the individual by virtue of painful and excessive menstruation, and which is probably functionless in respect of its primary function of child-bearing. Much interesting information upon these points is contained in Mr. BONNEY's paper, and facts are brought forward which appear to discount previous conclusions, based perhaps upon insufficient material. The most important physiological test of the success of an operation upon the uterus is naturally the ability to conceive and to carry the pregnancy to a successful termination. In a group of 77 married women within the child-bearing age at the time of operation, 30, or 39 per cent., became pregnant subsequently. Twenty-six conceived once, two conceived twice, and two three times. Twenty-five of the deliveries were natural. Two patients aborted and the remainder were delivered by Cæsarean section with the exception of one case where perforation was required for contracted pelvis. It may be said, therefore, that 34 children owe their existence to an operation which was substituted for the more radical procedure of hysterectomy and without presumably incurring a greater risk to the mother. It is true that in the series the necessity for Cæsarean section appears to figure rather prominently, but the remaining deliveries through the birth canal were uncomplicated and the contractile power of the uterus was evidently unimpaired. Furthermore, there was no evidence of weakening of the uterine wall and the scar showed no liability to rupture. It would, however, be interesting to know the extent of the operation which preceded the successful functional result. In how many of these cases were the fibroids multiple and interstitial in position? In how many was it necessary to incise the uterine cavity? What is the proportion of single tumours and how many were subperitoneal, if any? On the questions of the relief of menorrhagia, the development of new fibroids, and the necessity for further surgical interference Mr. BONNEY's figures appear to have disposed of the arguments originally put forward as contra-indications to myomectomy. His results taken as a whole are such as to warrant a revival of interest in an operation which in expert hands affords, as he says, an opportunity for individual ingenuity and craftsmanship compared with which routine hysterectomy is as mere mass production.

SICKNESS AND OCCUPATION.

SCIENCES differ from arts in possessing footrules for measuring the data with which they are concerned. Vital statistics provide the footrules for medicine, particularly for preventive medicine. Their study is the means by which we test our convictions that good health must be earned by daily activity, and that ill-health results from wrong living—if only we can ascertain how to earn health and what constitutes wrong living. Such studies are comparatively modern; and we are still, not inaptly, admitted by our Royal Colleges to practise the art and mystery of medicine. Variations in the environment of life, as represented by occupations, are recognised as providing data, regarding both sickness and death, which throw light on the origins of disease. Here such specific diseases as plumbism, silicosis, or skin cancer result from exposure to definite specific hazards; or general troubles, like bronchitis, rheumatism, or heart disease, by occurring unduly in certain occupations, may disclose the evil influence of some unexpected hazard. The methods pursued for detecting these hazards constitute an intricate study. First, standards of normality, both for mortality and morbidity, must be determined, against which occupational records can be measured. But normality, like truth, is an elusive entity, needing a high-priest to demand its definition, which, however, in this instance, has just been cleverly undertaken[1] by the International Labour Office at Geneva. A study has been issued which mainly displays the intricate difficulties to be mastered. Herein national pride notes that English records, investigations, and methods receive pride of place. Before occupational influences can be estimated, allowances must be made for age, sex, marital condition, race, social status, and density of population; each and all of which are well recognised as modifying the type and extent of both morbidity and mortality. Even then the way is not clear, for strenuous occupations, like mining, which may or may not be associated with some special risk, tend to recruit the strenuous; while occupations requiring little strength, like tailoring, but may be without risk, are pools wherein collect the weaker brethren, naturally prone to ill-health, either ab initio or as the result of exposure to risk at some other occupation. Next, morbidity must be classified according to disease, as far as possible on the lines internationally adopted for mortality; here consideration must be given not merely to the number of cases of sickness, but to the length of each case and to its method of ending, whether by recovery or death. The populations must present further problems, since trade prosperity or depression may rapidly change their size and age constitution; while rises or falls in the level of wages diminish or increase the tendency to claim sick pay. Of a truth many dragons beset the path to knowledge; but dragons are there to be overcome.

---

[1] Statistical Methods for Measuring Occupational Morbidity and Mortality. International Labour Office. Studies and Reports, Series N (Statistics), No. 16. 1930. Geneva. 5s.

The influence of occupational life is found to be obscured if standardisation for age is used; hence it is wisely rejected. Rather is study recommended, with instances given, of any excess morbidity or mortality over the standard—whatever standard, national or international, has been adopted—distributed according to age. Certain types of excess then become manifest which can be grouped. The first group contains industries having no selectional recruitment, subdivided as risk is slight or considerable. With slight risk, the curve of excess morbidity or mortality rises fairly steadily with age. With considerable risk, it rises with age until selection, by death or transfer to other work, stops the rise in the curve, which eventually becomes level or begins to fall. The second group contains strenuous industries which recruit vigorous lives, again subdivided as risk is moderate or severe. With moderate risk, the weakest are eliminated fairly rapidly, causing a rise in the curve in early life; then it steadies or even falls, until the more resistant elements are attacked, when it rises again, though it is likely to drop finally as age advances. With severe risk, selection by death or transfer is pronounced; hence, after a rapid rise, the curve falls steeply, but it always keeps at a high level. The third group contains industries which naturally recruit poor lives, subdivided similarly. Here, with slight risk, the curve starts high and thereafter falls gradually, but continuously, unless a constant inflow of weak persons so coincides with the risk as to keep the curve stationary. With considerable risk, the curve starts higher and then drops almost completely in a gradual slope, as more resistant elements remain to be attacked, while the main effect has been exhausted by the first attack. Thus, the feature common to group 1 is a long and gradual rise, to group 2 a long and steep rise, and to group 3 a long and gradual fall. On the whole, a convex life curve of excess mortality or morbidity is strong evidence that the excess is occupational in origin—an important dictum.

When the reason for an excess is examined according to disease, each disease is found with a typical excess curve, which, however, for each occupation is modified by selective forces; thus the excess curve for chronic nephritis shows two peaks of which the first is the higher; but the excess curve for pulmonary tuberculosis, after a steep rise, has one big peak. This study is a fascinating one in that it introduces new methods for detecting influences in life associated with varying types of invalidity and mortality. It is one for which Geneva deserves our thanks. Not the least valuable part is the way in which records from several countries, using national standards for comparison are assembled, contrasted, and made to yield their contributions to knowledge.

THE COURSE OF UNTREATED MALARIA.

The therapeutic use of malaria in general paralysis of the insane and other diseases has incidentally thrown new light on malaria itself, and at a meeting of the Royal Society of Tropical Medicine and Hygiene on Jan. 15th, Colonel S. P. James recounted some of the information thus gained since 1926. His paper chiefly concerned work done at the Horton Mental Hospital where malariotherapy has been employed in encephalitis lethargica and skin diseases, as well as in G.P.I., while there have also been accidental infections in the laboratory. The cases he reported were nearly all of tertian malaria induced by bites of *Anopheles maculipennis*, and the clinical picture was essentially the same whether malaria was added to another illness or not. In the tropics hookworm, syphilis, or some other infection is nearly always added to malaria, so that any suggestion that, because of such complication, the English work does not represent the normal course of a malarial infection can hardly be accepted.

Much has been learnt by letting therapeutic malaria "smoulder," by giving no quinine or only enough to stop fever without exterminating the parasites—a change in procedure based on the belief that the curative process is due not merely to the high fever but also to the continued presence of the parasites and their toxins. In half the smouldering cases spontaneous radical cure of the malaria has seemed to follow. In the rest James has described three febrile phases after the primary fever has ceased, and has proposed for them arbitrary labels which it will be convenient to use here. In the first eight weeks febrile attacks are frequent (recrudescences), in the next 16 weeks less so (relapses), and after that again frequent, especially between the thirtieth and fortieth weeks, occurring even as late as the forty-sixth week (recurrences). During the attacks parasites reappear in the cutaneous blood, or increase therein if already present. James regards the recurrence as very important from three aspects. There were 11 cases in which malarial infection seemed to have failed, and further attempts to produce it were not made because there was not the usual urgent need of treatment. In all these patients fever with parasites first appeared 28 to 44 weeks after they were bitten.

In JAMES's sense these were recurrences; recrudescences and relapses had been suppressed and replaced by a long latent period. They afford strong, perhaps convincing, evidence in favour of the view that the spring rise of malarial incidence in northern Europe, and the occurrence there of primary spring cases, at a time when the new anopheline brood is at least scanty, are due to recurrences of infections acquired in the previous autumn at a time when anopheles are abundant and their infection-rate at its height. We might thus describe the primary spring cases as "primary recurrences." Secondly, the recurrence is significant in immunity. At any time before recurrence had taken place, bites of infective anopheles could produce a malarial attack; after recurrence and subsequent spontaneous recovery they could not. But this immunity was singularly restricted; it was not even species wide; it was restricted to the particular strain of the tertian malaria parasite which caused the original attack. This interesting observation confirms, it may be noted, the views reached by the Malaria Commission of the League of Nations after its tour through southern and eastern Europe in 1924, that the exchange of malarial strains produced by mass migration of populations was a cause of epidemicity which has not been sufficiently stressed. Thirdly, the influence of recurrence, through its production of natural immunity, is held to be of primary importance in treatment. In all but exceptional cases JAMES considers the effect of quinine to depend on the acquisition of natural immunity, and this in its turn on what has happened in the primary attack. One who has suffered 10, 12, or more severe paroxysms has gone far to establish that immunity to his own parasitic strain which will show itself in spontaneous cure; in such conditions the good effect of quinine is marked. When, however, the drug has been given early it has interfered with these necessary mechanisms, and illness is apt to be protracted and marked by repeated febrile attacks. It is not believed possible "by any plan of quinine treatment to prevent recurrence *in the cases in which what has happened during*, or shortly after, the primary infection with sporozoits has made it an inevitable event in the illness." While subtertian malaria must be vigorously treated with quinine as soon as recognised, JAMES thinks that during the primary fever of tertian or quartan malaria the patient's interest lies in the withholding of quinine as long as possible. This implies the closest supervision to anticipate the possible advent of a grave bodily state and to prevent the possible spread of infection.

Colonel JAMES fully realises that a view so contrary to present usage is unlikely to meet with ready acceptance. Moreover, this country, as he pointed out, is not the place where final answers can be given to the questions he has raised; nor can these be reached by the mass methods of study at present employed—methods which use such average results as spleen and parasitic indices. The necessary study must be individual and intensive, and carried out in endemic areas where immunity or tolerance are clearly attained by those who survive in them. In the discussion which followed his paper the difficulties entailed in the suggestion were at once obviously and indirectly voiced, but it is not easy to see an alternative. His skilful work on malaria, deliberately produced and closely studied in controlled conditions, shows once again that important work on tropical diseases can be done in temperate climates. The Royal Society of Tropical Medicine may well congratulate itself on the valuable communications it has received on this particular subject, from WARRINGTON YORKE and J. W. S. MACFIE in 1923, from YORKE again in 1925, and from Colonel JAMES in 1926 and 1931.

ANNOTATIONS

THE FOSSIL MAN OF PEKIN.

THE discovery in 1929 of a brain-case in the limestone cave at Chou Kou Tien was the crowning chapter in a story which has been narrated in full in THE LANCET by Sir Arthur Keith.[1] But the tale deserves summary for its romantic quality. It begins with the stock-in-trade of a Chinese apothecary from whom in 1903 Prof. Max Schlosser received a fossil tooth that had been rescued from its destiny as one of the ingredients in some quack nostrum. This first suggested China as the home of ancient man. A geological survey was set up by the Chinese Government, and in 1918 the lack of students led Dr. Wong to invite Dr. J. G. Andersson, of Upsala, to join the expedition. One day Dr. Andersson overheard by chance the conversation of two of his native assistants who were remarking that he was foolish to waste his time on that spot when there was a much richer deposit of bones further north. He travelled north and found a quartz pebble. But quartz was not indigenous to that region, and he drew the conclusion that man had brought it there, and he dug for five years more. The immense collection of fossil bo that resulted was examined by Dr. O. Zdansky Prof. Wiman's laboratory at Upsala, and yiel two more teeth. The geological survey was t strengthened by the government, by the Pe Medical College under Prof. Davidson Black, a by the Rockefeller Foundation, and in 1927 unworn molar of a child of seven was found Dr. B. Böhlin. For the expert this was enough, it blended human and simian characters in a way hitherto known to us, and a new genus *Sinanthro* was created to hold men-apes of this class. A y later parts of two jaws and of a brain-case came light and confirmed the deductions made from t teeth. The Rockefeller grant was extended fo further three years, and finally in December, 19 the exhibit known as the "Pekin skull" was excavat

The majority of English people will never have t opportunity of seeing this specimen, for it is t property of the Chinese Government and will rema in China. All must feel, however, that the libe support afforded by this Government to the exp investigations which have led to the discovery a a model which might be copied with advantage many governments of countries in a less unsettled state. Certain criticisms depreciating the value of the find have emanated from Germany and from America, but last week a large number of people were able to hear from Prof. G. Elliot Smith, at University College, London, an authoritative valuation of *Sinanthropus pekinensis* which at once disposes of these less well-informed statements. Although for full details we must await the official publications, Prof. Elliot Smith, who has spent some time in China examining the specimens and locality, was able to show photographs of some aspects of the material and to give details of great general importance. The skull, which when seen from above has a decided resemblance to Pithecanthropus, can be placed definitely between this and the Piltdown specimen and, as Prof. Elliot Smith pointed out, bridges the gap between these and increases their evidential value in reconstructing the evolutionary history of *Homo sapiens*. The Pekin man died where he had lived, and lay where he died—from our point of view, fortunately—so that the natural deposits give the geological age with unusual certainty, and this can be placed early in the Pleistocene. Doubtless the establishment of this fact will have its effect on opinions held about the ages of the two other famous skulls.

---

[1] THE LANCET, 1929, ii., 683.

The front part of the skull resembles Pithecanthropus and the back Piltdown man; the owner was therefore nearer to the common ancestor than either of these. He was probably a youth of about 18. The eyebrow ridges are strongly marked and the frontal bones are flattened, but less so than those of Pithecanthropus; there is no mastoid process, but the articulation of the jaw is similar to that of modern man. As in Piltdown man, the parietal is thick, but the tables are separated by a distinct diploe and there is definite hollowing over the speech areas, suggesting a development of the parietal lobe of the brain which is absent in Pithecanthropus. The brain cavity is not on the whole much smaller than that found among living men, and it shows asymmetry such as is associated with right-handedness. A very curious and interesting point is that no trace whatever was found of instruments—except unworked quartz—despite careful search. An official report is in preparation.

CEREBRO-SPINAL FEVER IN GLASGOW.

Dr. R. J. Peters and Dr. W. C. Gunn, of the Glasgow public health department, have given an interesting account[1] of an epidemic of cerebro-spinal fever in that city during the first half of 1929. This is the third time the disease has visited Glasgow during the present century. The first and most severe was in 1906–08, when 1363 cases were reported and the fatality-rate of 910 patients treated in hospital was 74·8 per cent. The second, in 1915 and 1916, was a local manifestation of what was happening in most of the populous parts of Britain and was associated with outbreaks in military centres, in which the spread was attributable to overcrowding, poor ventilation, fatigue, and exposure. After 1916 the disease remained sporadic in Glasgow until the early months of 1929 when a series of cases, mostly acute, and some fulminating, occurred among boys aged from 14 to 18, who were in the habit of attending an ill-ventilated and crowded recreation hall. The total number of cases between January and June was 134, and the fatality-rate was 83·5 per cent. This being about 10 per cent. higher than in 1906–08, suggests that nothing was gained by the intervening improvement of methods of preparing and administering the specific serum. The incidence in males (86 cases) was almost double that in females (48 cases), but the disease was equally fatal to the two sexes. A table is given showing that cerebro-spinal fever is essentially a disease of small, overcrowded, and badly ventilated houses, its incidence being highest in houses of one or two rooms, and rapidly diminishing as the living space gets bigger. The Glasgow epidemic of 1929, like those during the late war, showed that segregation was of little use in the absence of measures to secure good ventilation and prevent overcrowding. As was to be expected, the better-class residential districts were completely exempt from the disease. Of the 22 patients who recovered 18 showed no sequelæ, while of the others, 1 was blind, 1 was deaf, and 2 suffered from headache and nervousness and were slightly unstable in temperament. In view of the attention which has been paid to the possible association of influenza with cerebro-spinal fever and acute poliomyelitis, it is noteworthy that a particularly severe type of influenza visited Glasgow in January and February, 1929, and that there was a small but definite epidemic of poliomyelitis in the city during July to October. But the incidence of influenza was not above the average in families where cerebro-spinal fever developed.

THE MENTALLY DEFECTIVE BLIND.

CHILDREN who are afflicted with either a physical or a mental defect can usually find suitable accommodation in this country to-day, but the unfortunate child or adult suffering from a double or a multiple defect often falls between two stools. A small but pathetic group among these are the children who are both blind and mentally subnormal. Their case has recently been pleaded before the Northern Counties Association for the Blind by Dr. Henry Herd.[1] In a sense, he remarks, every blind person may be said to suffer from mental defect, as his brain is deprived of the impressions received through the eyes, but when the mental make-up is normal nature compensates for the lack. If, however, the intelligence is dull, blindness will inevitably make the deficiency appear greater than it really is. The problem of helping these people, like the problem of mental deficiency, must be considered under two heads: the educable blind defective and the ineducable blind defective. The two classes are not sharply defined from each other, and the borderline cases are even more difficult to recognise than among the physically normal defectives. Nevertheless, there is a broad distinction upon which depend educational, legal, and administrative points.

The Northern Counties Association knows of 468 blind defectives in its area, of whom 42 are under 16 years of age, but Dr. Herd feels certain that this figure is much below the real number on account of the extreme difficulty of certifying a blind child as defective. He investigates the figures of blind schools and finds, as he expected, that a great many blind defective children are certified as blind only. There is, therefore, reason to think that the problem is a larger one than is generally realised. Dr. Herd recommends first of all a careful survey of the duller children in blind schools with a view to selecting the children who are not really profiting by the education given there. The League of Nations'

---

[1] Copies of the report are obtainable from the Secretary, N.C.A.B., 274, Deansgate, Manchester.

Report for 1929 on the Welfare of the Blind recommends that the educable should be left in blind schools and the ineducable dealt with under an organisation for the mentally defective. This, Dr. Herd thinks, is the best method; all mental defect, whether *complicated or uncomplicated*, should be under the care of the Board of Control. To leave blind certified defectives in the charge of an organisation for the blind is only justifiable if that organisation can give them something really distinctive. Work on this problem is being undertaken at the Ellen Terry Home at Reigate and the children there are under the care of the Board of Control. It is unfortunate, as Dr. Herd points out, that this home is receiving a very high proportion of low grade, almost ineducable children, while those on whom it might hope to produce results are still in homes for the blind normal child.

The ineducable case can be trained in simple acquisitions such as muscular balance, walking, speaking, and cleanliness, and will require a large proportion of staff to inmates and infinite patience and individual attention. Training should essentially *begin very early. Left to the well-meaning* but ill-directed training of a mother, such capacities as these children have are never elicited. The Ellen Terry Home takes some at the age of 2, and Dr. Herd suggests that classification should be reasonably satisfactory at the age of 7 at most. It is to be hoped that his suggestions will receive the attention they deserve.

MEDICAL EDUCATION IN THE SUDAN.

THE Gordon College, which acts as a central institution for education in the Sudan, appears to be well adapted to the country and to the type of work required of it. In the annual report of its activities up to Dec. 31st, 1929, attention is drawn to one of the more pressing problems, that of teaching the scholars English sufficiently fluent for them to master other subjects. This difficulty is experienced by all those who teach or lecture in the East; the remarkable proficiency with which their students can memorise long passages from text-books makes it hard to estimate their real comprehension of the matter they quote. A special effort is being made at the Gordon College to improve the English of students undertaking courses in engineering, accountancy, science, and other subjects in which a large technical vocabulary makes fluency essential. In the scientific section the lecturer in chemistry and physics remarks particularly on the language handicap of scholars in their third year; those in their fourth year are able to do more satisfactory work.

In 1929 ten boys completing the science course passed on to the Kitchener School of Medicine, and one was appointed laboratory assistant at the Wellcome Tropical Research laboratories. There can be little doubt that a central organisation under *an English staff, such as the Gordon College*, offers a foundation for the development of a high standard of medical service in the Sudan. Love of accuracy seems to be the attribute of the trained European mind which is least readily acquired by the Oriental, and which is first lost when supervision is relaxed. It is for this reason, perhaps, that those who have worked in the East hesitate to relinquish their jurisdiction to their native successors. Western medicine in lower Egypt, for example, is hardly likely to maintain quite the same standard since much of the direction passed into Egyptian hands as it did under entirely English guidance. A single instance will illustrate the difference in attitude: repeated specimens of fæces from dysentery cases sent by a practitioner to the public health department at Cairo for investigation were returned with negative reports by the Egyptian laboratory workers, until a personal application to the English director of the section led to investigation; 80 per cent. of the specimens subsequently sent and examined showed dysentery organisms. Whether the knowledge of his superior accuracy justifies one person in the perpetual supervision of another is open to discussion. It may well be that exactness can only be acquired by experience of the failure of slipshod methods; if such is the case, supervision can never be constructive, and is as misguided as the zeal with which a nurse buttons a child's boots to save time.

The importance of reliable early training, however, no one is likely to question, and appreciation of the work of the Gordon College is shown by the steady increase of scholars from 86 in 1918 to 554 in 1930. The need of more accommodation for scholastic work has led Dr. H. S. Wellcome to offer new buildings for the Wellcome Tropical Research laboratories, *at present occupying a wing of the College.* The work of the laboratories during the past 30 years has established a great record; striking results have been achieved in reducing the incidence of malaria and bilharzia in the irrigated area of the Gezira cotton scheme. The malarial splenic rate was reduced from 70 to 35 per cent. during the first six months of 1930, and the incidence of bilharzia from 5 to 0·2 per cent. Vaccines were prepared on a large scale, including typhoid, paratyphoid, antirabic, gonococcal, cholera, plague, *Staphylococcus aureus*, and *Staphylococcus albus*. The effect of d'Herelle's bacteriophage in bacillary dysentery was investigated on a large number of cases, and the conclusion was reached that it exerted no influence on the course of an attack.

THE ÆTIOLOGY OF PEPTIC ULCER.

PEPTIC ulcer becomes more and more prominent in medical literature with each succeeding year. Before the war we had the rise of surgical treatment; since then we have seen a partial return to more conservative methods. And along the lines of advance and retreat a battle has been fought which has left relatively little time for considering the original cause of the trouble. The comparative scantiness of ætiological work will make many of our readers turn with interest to a paper on p. 177, in which Mr. Laurence O'Shaughnessy records experiments on the production of peptic ulcer in animals. It is well known that whereas acute ulcers can be produced with considerable ease by a great variety of methods, it is very much more difficult to create a chronic ulcer of the stomach or duodenum in any animal. The methods by which this has usually been done have been chiefly those of Charles Bolton, who used gastrotoxic serum together with devices for preventing healing, and those of F. C. Mann and C. S. Williamson, who used complicated operations. P. T. McIlroy managed to produce acute ulceration in cats by subcutaneous injections of histamine, and his work wa confirmed by Büchner and others. O'Shaughness has extended these observations, and found tha chronic ulcers were not successfully produced b subcutaneous injection of histamine, but appeare in several animals in which local injection into th stomach wall followed by subcutaneous injectio twice daily. These ulcers closely resembled tho described by Bolton. Commenting on his resul

O'Shaughnessy refers to the natural origin of histamine as a product of protein disintegration, and links this to the development of ulcer in man following traumatic lesions such as burns, or the passage of dead bacterial products from septic foci into the blood stream. His work clearly requires repetition in a larger series, and certain other factors will require careful control. It has, for instance, long been known that histamine is a more powerful excitant of the secretion of hydrochloric acid than any other known product; the subcutaneous injection of a minute quantity of pure ergamine acid phosphate in man produces an immediate and striking flushing of the face, and an outpouring of highly acid juice into the stomach which is one of the most striking phenomena of experimental human physiology. It may well prove to be this factor which is of the greatest importance in the present experiments. The injection of any substance directly into the gastric wall must necessarily cause local injury, and if such an injury is followed by the repeated violent stimulation of the gastric secretion, it is perhaps inevitable that a chronic ulcer will follow in an appreciable proportion of cases. These considerations make it necessary to accept O'Shaughnessy's conclusions with the same reserve with which they are put forward.

MONOCULAR VISION AND MOTOR-DRIVING.

A TIMELY investigation of monocular vision is reported by the Belgian ophthalmologists, L. Weekers and R. Hubin.[1] For many purposes of ordinary life the absence of binocular vision is scarcely noticed, or may be in great measure compensated by means of monocular parallax, accommodation, and linear perspective. But this compensation is by no means perfect, and it is often noticed that the one-eyed have difficulties in such actions as pouring water from a jug into a tumbler, or that they require more time and expend more effort in performing tasks which require fine adjustment. The avoidance of a collision by the driver of an automobile is just such a task, and the element of time in making the decision as to what to do when a collision is imminent may be all important. A simple test which will prove beyond any question just how perfect or how defective the capacity for correctly estimating distance is in any individual is highly desirable. Such a test is employed by the Belgian military aviation authorities. Three black threads are placed vertically, the centre one being fixed while the two lateral ones can be moved into the same plane with it by means of a string held by the subject to be tested, who is seated at a certain distance away. A series of experiments was carried out: (1) on emmetropes; (2) on corrected myopes; (3) on corrected hypermetropes; (4) on subjects who had recently lost the sight of one eye; (5) on subjects who had for many years been one-eyed; and (6) on those with amblyopia ex anopsia of one eye. In the first three classes tests were made first with both eyes open and then with one eye closed. By means of the apparatus it was possible not only to test the presence or absence of any defect of binocular vision but also the amount of the defect when present. The conclusions arrived at were as follows: First, that stereoscopic vision is defective in the one-eyed (as might be expected), even when the loss of one eye is not recent. Secondly, that apart from high hypermetropia the existence of ametropia, if fully corrected and with good visual acuity, has no practical bearing on the degree of stereoscopic acuity. It was noticed that in the case of the one-eyed, the amount of the defect of binocular vision was very variable if the experiments were repeated, whereas in the case of the normal subject with binocular vision the results were fairly constant. Only very exceptionally was a one-eyed subject able to give satisfactory answers, and this was so even when the strict conditions under which the tests were carried out were relaxed and the subject was permitted to move his head.

OPERATIVE TREATMENT OF AURAL VERTIGO.

IN 1904 Richard Lake first operated on the labyrinth for the relief of vertigo. Since then the various operations tried have varied from the mere opening of the external semicircular canal, with a view to relieving endolabyrinthine pressure, to exenteration by combined superior and inferior labyrinthotomy. The smaller operations often fail to achieve their object, while the more extensive ones are formidable and even dangerous. Mr. Sydney Scott, in experiments on pigeons, destroyed the function of the semicircular canals by the injection into them of alcohol, and this has induced Mr. W. M. Mollison[1] to try a similar method in the treatment of severe vertigo of aural origin. He finds the operation a very simple one, for the healthy mastoid bone is almost bloodless; the prominence of the external semicircular canal is exposed and opened, and 0·5 to 1·0 c.cm. of absolute alcohol is injected in a forward direction with a lacrymal syringe. Mr. Mollison has performed this operation on eight patients, six of whom suffered from non-suppurative aural vertigo, and two from vertigo following the radical mastoid operation. One patient, though improved, has never been entirely free from symptoms; all the others have been free from attacks of giddiness, one for as long as ten years. In some cases there is considerable vertigo for a few days after the operation.

AN EVANGELIST OF PASTEURISATION.

Nathan Straus, who has just died in New York, was one of three brothers who shared an absorbing interest in Zionism with a genius for commerce which, we are told, made it impossible for them not to make money. But Nathan, the younger brother, had a second interest which was a craving for truth, undiminished by commercial success, and when he made money he spent it on the children of others. Some 40 years ago he became convinced that raw milk was killing children in New York and that the risk of drinking milk could be reduced to a minimum by the process of pasteurisation. He accordingly gave his mind to organising a practical system of pasteurisation in New York, and the first laboratory to this end was established in 1893 with a simple equipment for furnishing modified and pasteurised milk in bottles from which it was to be given direct to the infant. In 15 years there were 17 Straus milk depôts in New York City from which more than 3 million bottles of milk were sent out annually, and Nathan Straus attributed with some justice the decline of New York's infantile death-rate from 96·2 per 1000 in 1892 to 59 per 1000 in 1906 to the employment of pasteurisation. Later he designed a pasteuriser for home use, known by his name, which was regarded as both efficient and foolproof. Not content with this achievement in New York, Mr. Straus discovered a village of 4000 inhabitants near Heidelberg with a death-rate among children under two of 460 per 1000; there he set up a plant supplying all children of this age with free pasteurised milk when, it is stated, the death-rate promptly fell to less than 200 per 1000. He also gave a pasteurising plant to the city of Dublin which has since been maintained by the Women's National Health Association. Little by little his work gained public recognition and by 1916 pasteurisation was either obligatory or officially encouraged in 46 of the 52 largest cities in America. Nathan Straus would have been greatly cheered had he been able to appreciate the significance of the manifesto by Lord Dawson and others which appeared in our columns on Dec. 13th last, for his gospel was the universal recognition for pasteurisation as the immediate practical method of ensuring the safety of the milk-supply. It never occurred to him that this measure was a second best or that it could hinder the provision of an ideal supply of cleanly produced milk.

DISTRIBUTION OF VIRUS AFTER VACCINATION.

A SERIES of detailed observations on the course of primary vaccination of 86 infants of 4 to 20 months of age is recorded from Germany.[1] In the great majority of the infants, the vaccination ran a normal course, and the virus was detected in the blood on the sixth day in 75 per cent., but never beyond the tenth day, nor was it ever found in the cerebro-spinal fluid in 56 examinations, nor in the throat swabs from 61 infants taken between the third and fifth days. Six infants had symptoms of nervous disturbance which the authors do not more exactly define and in five of these evidence of unusual distribution of the virus was obtained; twice it was recovered from the cerebro-spinal fluid (on the sixth and twelfth days) three times unusually late in the blood (on the fifteenth, seventeenth, and twenty-ninth days), and twice from the throat. From these observations they draw the conclusion that post-vaccinal encephalitis is very likely associated with unusually extensive distribution of the virus in the body. They think that this conclusion supports the recommendation of Hekman and Paschen that antivaccinia serum, either from vaccinated human beings or specially immunised horses, should be used intravenously or intramuscularly in post-vaccinal encephalitis cases. Whatever the explanation of the value of such serum may be, the procedure appears to be supported by the published results.[2] Ledingham and Petrie have prepared antivaccinia serum from horses for this purpose.

AN ANCIENT AND HONOURABLE CALLING.

THIS year is the Jubilee of the Midwives Institute, and its Council is appealing for a fund as a tribute to those who in 1881 determined to obtain recognition, training, and an improved status for midwives—then an almost untrained body of women, entirely unorganised. In the early 'nineties the Institute raised a guarantee fund of £1000 to promote the first Midwives Bill (1890), and initiated the long struggle to obtain State recognition which culminated in the Midwives Act, 1902. It is due to these efforts that the trained independent midwife and the district nurse midwife exist to-day. The Institute is managed by midwives for midwives, and is a self-governing body of professional women whose object is to watch over the interests of the practising midwife, to promote her efficiency, and improve the status of the profession in every way. In view of the findings of the Departmental Committee on the Training and Employment of Midwives, it is essential that the midwife should be competent to take her part in reducing maternal mortality and morbidity and infant mortality. She is an essential unit in any scheme for a national maternity service, and it is in order to provide the mothers of this country with the best possible care that the Institute is promoting the further education of midwives. The standard of training has already been raised through post-graduate courses of instruction and the initiation by the Institute of a diploma in teaching. *One of the most urgent and vital needs* is to further and develop these educational activities. Funds are needed for further development of this educational work and for adequate premises to permit of its extension. The money collected through the appeal will be presented in June next to Miss Rosalind Paget, the last surviving founder of the Institute, who has acted as its hon. treasurer for 40 years. The address of the Institute is 12, Buckingham-street, London, W.C.2.

THE DOSAGE OF DIGITALIS.

"LET the medicine be given until it either acts upon the kidneys, the stomach, the pulse, or the bowels; let it be stopped on the first appearance of any of these effects." This advice, given by William Withering, who wrote the first detailed study of digitalis 150 years ago, is quoted by H. Gold and A. C. DeGraff [1] in a recent paper on digitalis. They lay stress on its importance and point out that obedience to this ancient precept ensures that the patient is fully digitalised, whereas some methods used by modern physicians result in insufficient or excessive digitalisation. They then discuss the vexed question of the dosage necessary to produce the optimum therapeutic effects in patients with auricular fibrillation and cardiac failure. The degree of cardiac failure is the factor of greatest importance in estimating the dose required, and for practical purposes they arbitrarily divide their patients into two groups: those showing signs of failure when at rest, and those who only develop signs of failure after a certain amount of exertion. In the first group, rapid digitalisation with the largest doses that can be tolerated without toxic symptoms gives the best results; but in the second group such high dosage is usually unnecessary because there is a wide margin between the amount of drug required to produce full therapeutic effects and the amount that can be tolerated without toxic symptoms. In this second group, once the initial effect has been obtained, a relatively small dose can be continued for daily maintenance with the maximum therapeutic effect. The usual explanation of this is that the smaller doses are necessary in order to maintain the high "effective concentration" of the drug in the body produced by the larger. Gold and DeGraff, however, set forth evidence to show that the "effective concentration" necessary to maintain full therapeutic action is usually much lower than that required at the beginning of treatment. They also point out that there is another effect to be considered after the circulation has been restored—namely, the tendency for improvement to be maintained, irrespective of digitalis treatment. This varies with the different kinds and degrees of cardiac damage, and in their opinion plays a significant part in determining the dosage required in the later stage of treatment. The wide variation in dosage recommended by different authors is probably due to the fact that the same preparation may vary much in potency. Such variation may sometimes escape detection in the wide margin between the minimum dosage which produces the full effect, and the maximum tolerated without toxic symptoms.

VITAL STATISTICS FOR 1930.

The Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infant mortality during the year 1930.

—	Birth-rate.	Death-rate.	Infant mortality-rate.
England and Wales ..	16·3	11·5	60
107 county boroughs and great towns including London	16·7	11·5	64
159 smaller towns ..	16·2	10·5	55
London	15·7	11·4	59

The smaller towns are those with a population in 1921 of 20,000–50,000. The death-rate for England and Wales (which is based on the estimated population in 1930) relates to the whole population, but that for London and the two groups of towns (based on the 1929 estimate) to the civil population only. Birth-rate (live births) and death-rate (crude) are per 1000 population, infant mortality-rate per 1000 live births.

The Registrar-General remarks that the birth-rate is the same as that for 1929, which was the lowest recorded. The death-rate is 1·9 below that for 1929 and is the lowest on record, being 0·1 below the rate for 1923 and 1926, the previous lowest. The infant mortality-rate is also the lowest on record, being 5 per 1000 below that for 1928, the previous lowest, and 14 per 1000 below that for 1929. These provisional figures, which are not likely to require substantial modification, have been issued for the information of medical officers of health and others.

SELECTED READINGS.

Two recent historical books[1] should be read by every medical man who wishes to know how physiology reached its present state and in what manner pathology is indebted to physiology throughout the ages. The books run on parallel lines and are complementary the one to the other. Dr. Fulton, a Rhodes scholar and formerly a Fellow of Magdalen College, Oxford, is peculiarly happy in the selections he has made, and shows evidence of considerable research. He draws attention to the work of several physiologists which was in danger of being forgotten or was never adequately recognised. Examples are, Alexander Philip Wilson-Philip, who practised in London about 1830 and was the original of Dr. Firmin in Thackeray's "Adventures of Philip"; Charles Marie Benjamin Rouget of Montpellier, whose researches on the contractility of the capillaries appeared in 1878; and Alexander Stuart, the first Croonian lecturer at the Royal College of Physicians in London. The method followed is similar in each volume. General principles are dealt with first and, in the case of physiology, the circulation of the blood; the capillary circulation, respiration, digestion, and the central nervous system are considered. The survey begins with Aristotle B.C. 350 and ends with Banting, Best, and Macleod, who drew attention to the internal secretion of the pancreas in 1922. Prof. Long considers the history of pathology from Hippocrates to Virchow and shows incidentally how numerous and important were the advances made by English-speaking physicians. The chosen passages give the ipsissima verba of the writers translated, when necessary, into idiomatic English and to each is added a short biography, a portrait, a copy of the title page of the book quoted or a facsimile of the passages containing the Master's summary of his work. The method is ingenious, interesting, and arresting, for it brings the reader into direct contact with authors whose works are often quoted but rarely read. The publisher supplies a final page which takes the place of the sixteenth century colophon setting out various facts of great interest to the bibliographer. It shows that much thought has been given to the paper, type, illustrations, and binding, with the result that each book is light in weight, easy to handle, and pleasant to read. Dr. Fulton's index is so good that, as was said of Dr. Thomas Willis's "Practice of Physic" (1670), the book is "fitted to the meanest capacity by an index."

INDEX TO "THE LANCET," VOL. II., 1930.

The Index and Title-page to Vol. II., 1930, which was completed with the issue of Dec. 27th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of The Lancet, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. W. A. Hopkins to be Surg. Lt.-Comdr.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Sub-Lt. W. D. M. Millar is promoted to Proby. Surg. Lt.

G. H. Sellers is entered as Proby. Surg. Lt., and attached to Mersey Divn., List 2.

ROYAL ARMY MEDICAL CORPS.

Maj. (temp. Lt.-Col.) C. H. Denyer to be Lt.-Col., vice Lt.-Col. S. L. Pallant to ret. pay.

Maj. and Bt. Lt.-Col. H. M. J. Perry to be temp. Lt.-Col.

Maj. P. G. M. Elvery is placed on the half-pay list on account of ill-health.

Maj. J. A. Bennett retires on ret. pay.

Lts. T. N. Fogarty and J. C. Macfarlane resign their commns.

TERRITORIAL ARMY.

Capt. E. A. Wilson resigns his commn.

Lts. W. H. Gratrix, R. E. Davie, R. G. Morrison, and K. V. Bailey to be Capts.

Lt. W. A. Lister (late K.R.R.C.) to be Lt.

The King has appointed Capt. Walter Hugh Critien, I.M.S., to be His Majesty's Vice-Consul at Seistan.

A POST-GRADUATE COURSE

MOTIVES AND MECHANISMS OF THE MIND.*

IV.—MIND: ITS EVOLUTION.

THE OVER-IMPORTANCE OF "THIS" AND "NOW."

PERHAPS the greatest cause of our lack of proportion both in viewing our own lives and in our regard of history in general, is the fact that the *now* in which we live is so vivid that we are unable to see it in perspective with past events. If we have been away for a summer holiday living under unusual circumstances and sharing the life of a new environment, it is very difficult, after we have returned to the usual routine of everyday life, to imagine that the life which we have left is still continuing undisturbed in spite of our absence. We feel as if the place where we are not must be less vivid than the place in which we are. This is also comparable to the way in which we usually try to understand others as if they were like ourselves. Our awareness of life, at any given moment, is limited to *me, now.* It is obvious, however, that there is really no objective difference in the vividness of experience as between what *I* experience *here, now*, and what *he* experienced *there, then.* The difference is merely a subjective one of *my awareness*, but to me the difference is so great that I am very apt to ignore the equal importance of *him, there, then.*

If we realised the fact that two events taking place at intervals of time and space were relatively equally important in all but our awareness of them, we should be able to preserve a sense of proportion, and perhaps also a sense of humour, which should save us from an exaggerated sense of personal self-importance. But *me* and *now* together share the importance of coexistence and vividness, and so we are liable to forget the extent to which *me, now* is only a development of *me, then. Now* is the growing point of our individual development, as it is also the growing point of history. But we are inclined to value it in a two-dimensional way, ignoring the time factor. We do not comprehend the way in which *I* and *now* are only built up as the sum of past experiences. But it is in fact true, that the value of *me, now* is largely determined by the value which has been attached to past experience.

For example, suppose that *I* am afraid of this dog *now*, it may be that this dog is a particularly fierce dog and that I am actually in danger of him biting me, but my awareness of my danger depends upon my previous value of danger and my previous value of dogs, and also, it should be added, my value of myself. But past experiences tend to be forgotten in our valuation of the present situation, however important they may be. The child who is afraid of dogs does not necessarily remember any occasion upon which a dog injured him or frightened him or he heard that it was dangerous. He is only aware of feeling afraid of this dog *now*, however harmless the animal may be. Every event tends to be valued by itself instead of as the last link of a chain which has been developed in inexorable continuity.

CONTINUITY OF DEVELOPMENT.

The development of our lives is a continuous process beginning before we are born and ending, so far as our present awareness extends, at death. It is important to realise the fact that this development is initiated prior to what we are aware of as individual experience. The nine months development of the fœtus in the uterus must be considered as part of the continuity of life's experience. It is perhaps associated, for instance, with our ultimate evaluation of rhythm and music. The most primitive source of rhythmic satisfaction is probably the tom-tom, with the first beat louder than the second. Our earliest experience of the "tom-te" rhythm is probably intra-uterine, the developing ear of the fœtus becoming accustomed to the sound of the maternal arteries. All later experience of "tom-te" rhythm, and its associations, must be evaluated upon the basis of this earliest experience. Similarly, in order to appreciate the psychology of the emotional value and recuperative qualities of a holiday at the seaside, it is necessary to associate them with our earliest experience of the comfort of water—namely, during our intra-uterine experience.

But the continuity of mind development begins from a still earlier point than that of conception. I is as if two converging lines traced back to a single point are found behind it to diverge beyond to an ever-widening infinity. This earlier experience which determines our valuation of *this* and *now* is altogethe beyond and outside our own lives. *It is derived from the sum of racial experience inborn within us as par of our hereditary equipment.* The chick that can peck seeds as soon as it comes out of the shell i reacting to a deeper pattern than any that has been acquired out of its own limited experience. It i an inborn tendency of behaviour, acquired from the sum of innumerable experiences by great numbers of its species in the past. We are born equipped with a certain anatomical pattern which is independent of experience, with organs and nerves which develop and fulfil their function according to an inborn law Similarly, there are the inborn instinctive patterns with their associated feelings shared by all individuals of the species, operating in each in a similar fashion and towards a similar end. These are more than individual experiences, and so the value which we give to this and that, to *now* and *then*, will depend upon hereditary instinctive and emotional factors, a well as upon the sum of those experiences which we have acquired during our lifetime.

FREE WILL AND DETERMINISM.

Freud, from his own psychological standpoint, has put an end to the age-long controversy between free will and determinism, by declaring finally that free will is an illusion and that our behaviour is determined by forces and experiences of which we are mainly unconscious. His conclusions will not satisfy the great majority, for if free will is only an illusion it is an illusion that will die very hard. Without committing ourselves one way or the other, it is at least necessary to recognise a greater degree of what is known as "determinism" than is generally recognised. Much that we consider to be free will is found on investigation merely to be the last link of a chain, the origin of which is traced back to unconscious sources. Freud proved to his own satisfaction that if an individual were asked to think of a number of three digits and thought of "257," the choice of the number was in fact due to various selective motives of which the individual himself was unaware, and that he could not under the circumstances have chosen any other numbers than those which he did.

---

* A course of 12 lectures delivered under the auspices of the Tavistock Clinic, Tavistock-square, by Dr. E. Graham Howe during the autumn session of 1930. The first, second, and third lectures of the series appeared on Jan. 3rd, 10th, and 17th, 1931, respectively

Similarly, where there is apparently an option as to which path shall be chosen, the actual selective factor will be found to be unconscious, rather than a conscious exercise of free will. We are the victims, not of an external fate, but of an internal compulsion, the origin of which lies outside our own experience, perhaps—and probably outside consciousness also. Seeing individual life in this perspective, we must be willing to forgo some of the illusion of free will, retaining it however as an ideal which may be obtained when we are free—if ever—from this unconscious motivation.

Association.

The previous paragraphs have dealt with continuity, but continuity by itself does not account for the development of mind. A second factor is required in order to give us a balanced aspect of mind in both time and space. Besides proceeding in continuous lines, the development of mind takes place through what is called "association." The process of association is one by which innumerable cross-references and comparisons are made, experiences being split up, evaluated, and compared with one another. We then conceive of the mind as being a network of associations, the number of potential links being infinitely extensible as the process of splitting up and comparison is developed.

The factor which determines the associative link is one of a common *emotional value.* "There is something about *this* that reminds me of *that*, because I feel somewhat similar about *this* and about *that.*" To say that there is a common quality of *meaning* puts the same idea into a different form, because meaning is a more abstract and highly differentiated value of a primary quality of "feeling about" a certain object.

Association may be of many different kinds, but is always based upon some quality of similarity. For instance, "bell, tell" has an association by virtue of a similarity of sound without regard to meaning. "Bell, tone" has an association from the idea of "bell" to a certain quality of its function. This is an association upon a more abstract level of ideation. "Bell, bicycle" introduces a more individual feeling quality. I would not associate "bell" with "bicycle" unless "bicycle" at the moment possessed an individual value of considerable importance to me. Another person might associate "bell" with "visitor," if one were expected, because that would possess a stronger individual valuation.

The method introduced by Freud, known as "free association," has been of inestimable value in determining the cause of a patient's feelings about any particular event. No event stands alone, because any event must strike many links of association with other events similar or different. The value to the patient of *this* event will therefore depend upon the links of association. For instance, fear of this dog *now*, is linked by an association with that dog *then.* Perhaps the fear of dogs has led, by an extension of the association, to fear of other animals. Feelings originally associated with only one object tend to become extended by further association with an ever-widening group, linked by some bond of similarity. The free association method consists of obtaining the patient's immediate and uncensored reaction to a stimulus word. The patient, being in a relaxed and passive state, lets his mind respond to the stimulus word with the first association link and this may be continued with other associations. What is happening is a quite irrational and unconscious process, but it is nevertheless logically determined. The patient is merely telling the doctor that to him there is some common quality of feeling between each of the words which he is saying and the one which preceded them. A similar result is obtained by saying to a patient, "What does so and so remind you of, or what do you feel about so and so?" In each case we are trying to trace back, through links having a common quality of feeling, to the original source from which the feeling sprang.

TRANSFERRED AFFECTS.

We can now consider what is meant by the term "transferred affect," which is an extremely important one for our understanding of psychological medicine. The "affect" is the feeling value which becomes transferred under certain circumstances to an associated idea. For example, the feeling which I originally had about *that* dog which frightened me becomes transferred from that dog to all dogs and so to *this* dog. The transferred affect may be carried still further to include other four-legged animals, in which case the ultimate result of the original experience of being frightened by the dog is that I have now become afraid of all four-legged animals. The feeling of fear "affect" has been transferred from *that* through *these* to *this*, and from *then* to *now*, and my value of *this, now* is determined by the transferred affect from *that, then.*

From another point of view the conception of free association and the transferred affect may be usefully linked with that introduced by Pavlov and used a great deal in the behaviourist school of psychology—namely, the "conditioned reflex." The conditioned reflex is one that has been acquired as a result of an experience being built on, as it were, to an original experience.

Salivation in dogs is a simple reflex consequence of the sight of food. If, at the same time as food is presented a bell is rung and this experience is repeated on a sufficient number of occasions, the bell and food become so intimately associated that in the absence of food the bell becomes an adequate stimulus to produce the reflex of salivation. The bell stimulus and salivation response is then said to be a conditioned reflex.

Examples have been given already in previous lectures of association and transferred affects. For instance, the patient who was terrified of all policemen because he felt that they were going to punish him, had transferred to "policemen" that feeling which had originally been associated with his father at the time of the guilty experience with his elderly female relative. Similarly, the patient who wrote the notes about the umbrella and her shoe, had transferred affects from her father's person to the umbrella, and from her own to the shoe through unconscious feeling association. Affects are usually transferred in this way to representative *symbols*, which then have the feeling value of the original object.

COMPLEXES.

The conception of complexes is also a very fundamental one in psychology. Unfortunately some confusion has arisen owing to the fact that the word has been used to cover two rather different meanings. On the one hand, any group of ideas associated with a single feeling, such as love or patriotism is, by some psychologists, described as a "complex" and the word is then used synonymously with "sentiment." This use of the word is gradually and wisely being abandoned. The use of the word "complex" should be limited to *pathological* association of a feeling with an object—in other words, to those cases in which a transferred affect has taken place. For example, in the cases cited above, one patient has a policeman complex, another an umbrella complex, because the quality of feeling tone has been transferred from the original object to some other object to which the feeling does not in fact rationally belong.

The word "complex" is also used to describe certain pathological states of feeling which are not simply due to transferred affects, such as the "Œdipus," "Electra," and "inferiority" complexes. In each of these transferred affects have taken place, but the particular complex indicated by these names shows a certain pattern of associated feelings, and tendencies towards certain patterns of behaviour. They will be dealt with individually in this and successive lectures.

TRAUMATA.

In the early days of Freud's psychological work he was largely interested in certain phenomena of hysteria, and he came to the conclusion that he was dealing with cases in which "transferred affect" had taken place from some previous injurious experience which had usually occurred in childhood. Pathological states of feeling and behaviour were thought by him to have been caused by some definite previous injurious experience which was called a "trauma" or wound. His further investigations showed him that his earlier results were in many cases at any rate due to a fallacy, the patient having described to him events as if they had actually taken place which were, in fact, only products of an hysterical imagination (i.e., wish-fulfilment, as in the case of rape mentioned in a previous lecture).

However, the importance of traumata or injurious experiences in the ætiology of psychopathological developments again came into great prominence during and after the war. It was found that the shock of being blown up or some particularly terrifying episode had caused the development of the pathological state, and the investigation of ætiological traumata assumed further importance. It was found that by inducing the patient again to live through the injurious experience, an abreaction or emotional recapitulation of the events took place which, by reassociation and reorganisation, restored the patient's feelings and behaviour to the normal.

By itself, however, this was in many cases found not to be enough, and once again the ætiological importance of traumata was found to be insufficient. Why did certain cases develop shell-shock whilst others did not? Besides the injurious episode, there was always the personal psychological factor and, as mentioned already in the first lecture, the type of case which was most liable to shell-shock was the one who was unable to face the fact that his feelings were those of fear. It became apparent therefore that abreaction of the experience was not in itself all-important, but effective therapeutics required an investigation and elucidation of the patient's individual psychological reactions.

The importance of traumata has nevertheless remained exaggerated, and it is very common indeed to find patients, especially those who have read a little psychological literature, expecting to have all their troubles cleared up by the discovery of some single important event of childhood or infancy which had long been forgotten. But this is very like an infantile wish-fulfilment of "something for nothing." It is perfectly true that traumatic episodes have sometimes occurred, and, especially when they have become forgotten, beneficial results occasionally bordering upon the miraculous have been derived from their recollection and reassociation. On the other hand, it must be remembered that the patient's individual psychology still remains an all-important factor, and that there are many cases in which the trouble lies, not in any single experience, but in the patient's individual tendency *to react to normal experience in an abnormal way*.

There is another way in which the idea of trauma still remains useful, and this is when it is extended to include those cases in which the injurious experience, instead of happening in a single event, has been spread over many events and over a long period of time. The "single event" type of trauma might be, for example, some premature injurious sexual experience or a thrashing from a drunken father. A far more common type of injurious experience, however, is that which is spread over a long period of time. The father, instead of beating the child *once* in drunken anger, might have been one of those stern, orthodox, patriarchal parents whose influence upon the sensitive emotional system of the child is far too crude and severe to permit of its normal development according to its own inward light. The sentimental, tender-hearted, over-affectionate type of doting mother is again an example of an oft-repeated injurious experience, which can have the most devastating effect upon the child's ultimate development. The "spoilt child" type is therefore the commonest result of repeated "traumatic" experiences in infancy and childhood.

"Recapitulation."

In order to understand aright the development of mind we must know what is meant by the principle of "recapitulation." Recapitulation is the process by which an individual life repeats a line of development which represents a sum of previous racial experiences. The best example of recapitulation is that which takes place in the development of the fœtus *in utero*. During this nine months the fœtus passes through all those stages of development which have marked the biological progress of the human race in the ultimate evolution of humanity. It begins as a unicellular structure which, after dividing into many cells, eventually becomes differentiated into fish-form, frog-form, mammal-form, monkey-form, and finally human form. It is as if the time factor has been infinitely speeded up, and within the short space of nine months the racial evolution of many thousands of years is repeated in the individual. But recapitulation is not limited to the intra-uterine life. Progress is continued after the child is born, and as the development of the nervous system is completed the child becomes able to make the complicated coördinated movements of walking and talking.

It is nonsense to talk about *teaching* a child to walk; it learns as soon as its nervous system has been developed far enough for it to do so. The same remark applies to much other so-called teaching, which can never hope to do more than develop innate potentialities. It is therefore not sufficient to regard these developments as being due to something that the child has been taught. It is quite true that example and encouragement are useful, but they would be of no use were it not for a primary inborn capacity which must develop to a certain stage before such coördinated behaviour can be attained.

If we appreciate rightly the importance of recapitulation, we shall realise that education must always be secondary to it. The capacity to learn depends upon the state of development to which the individual has attained, and this capacity for development represents the stage of *recapitulation* which he has reached. It is very important therefore to recognise the existence of stages of emotional development in infancy, childhood, and adolescence, which are right enough at certain ages, and will be grown out of in due course, if all goes well. It is adult interference which too often prevents normal development, either by snubbing criticism or sentimental prejudice. The adult easily takes upon himself the task of curbing and criticising conduct of which he does not approve in the child, trying to introduce his own ideas which are not necessarily correct, by teaching them as an external pattern to which the child is expected to conform. But this method is fundamentally incorrect. The child does not require to be taught, but *educated*—that is, to be allowed to develop and express all that he *socially* can, that is concurrent with his own recapitulatory phase at any particular moment. It is perhaps wise to stress the word *socially* in view of certain exaggerated beliefs in letting children have their own way. *Social adjustment* must always be part of individual development.

ENDOGAMY.

We can now consider some of the phases of emotional recapitulation which appear during individual development. It is only possible to outline their general principles, recognising some degree both of modification and similarity as essential in different cases. It is not wise to make cast-iron generalisations where human life is concerned. But it is certainly true that, through our understanding of emotional recapitulation, it is possible more clearly both to foretell and to understand much of human behaviour that would otherwise be obscure to us.

The axiom we are about to consider may be put as follows: "Behaviour cannot be understood merely in terms of individual experience." It is much more, because the individual starts with *inborn feeling and behaviour tendencies*, developing at different ages, originating in a distant past, and therefore not always apparently relevant or suited to the circumstances in which they occur. The individual's awareness of his recapitulation can only be in terms of his immediate experience. He does not know that he is living again the racial past, but he is more or less aware of certain feeling states which he can only consider as a reaction to his experience of his environment. It is to these feeling patterns of emotional recapitulation that we must now direct our attention. They will be common to all individuals, in the same way that anatomical and nerve patterns are common to all individuals, but will be subject in the same way to individual variation.

In order to correlate the emotional development of infancy with recapitulation of a previous racial experience, it is necessary to go far back in the history of evolution of the race. The infant is in a position of primitive dependence, and its environment is limited to experience of the intimate family circle. There is no doubt that the most intense emotional experience of infancy is associated with the mother or mother-surrogate for both sexes, the father being of secondary importance. This fact of the primary satisfaction derived from the intimacy with the mother through the food-function is of the greatest importance in individual psychology. It throws the infant literally "into the arms of" the mother and from this primary basis is derived all later experience of emotional gratification. We must remember, in the case of the boy, the difference of the two sexes, and this will lead us to anticipate certain differences of ultimate evaluation as between the boy and the girl, because her primary association with the mother does not show the same sexual polarity.

Recent anthropological researches suggest that in the origin of man there is a common factor in what is known as the "endogamous principle." Whatever type of civilisation is investigated, the further the search goes back, the more evidence is there of the earliest state of tribal organisation being "endogamous"—that is, being based upon a marriage system within the limits of the family or tribal circle. It is therefore suggested as a working hypothesis that this endogamous orientation of primitive racial emotion may be associated through recapitulation with a similar endogamous orientation in individual infancy. Firstly, it is a fact of individual experience that those who matter most in infancy are mother, father, nurse, and family. Secondly, it may be granted that it is the earliest experiences which leave the deepest impression upon the sensitive plate of the developing mind. Thirdly, the outstanding importance of this phase is the commonest clinical experience of psychologists. It is therefore both interesting and helpful to link it up tentatively with past racial experience, as an example of recapitulation.

In Egypt it was the custom for fathers to marry daughters, mothers sons, and brothers sisters. Marriage outside a very limited circle was under this system regarded as immoral. The system of endogamy was still in force in Egypt at the time of Moses' leadership of the Israelites. Much of the Mosaic law was based upon his appreciation of medical factors, and amongst his other qualities for leadership Moses must be considered as a biologist He seems to have appreciated some of the principles which are at the present day in common use by stock-breeders. It is well known that inbreeding from healthy progressive stock may be used to increase their desirable characteristics, but if there are decadent factors then inbreeding will intensify the bad characteristics just as much as it may intensify the good. Apparently Moses believed that inbreeding in the Egyptian stock was giving rise to a progressive decadence, and we may imagine that it was for this reason that he ordered the Israelites: "After the doings of the land of Egypt, wherein ye dwelt, shall ye not do." (Leviticus, xviii., 3.)

The Mosaic law is at the present day standardised in English Church Law and appears in the English prayer-book as the Table of Kindred and Affinity, in which the taboo of endogamy has gone so far as to forbid marriage with the deceased wife's father's sister and the marriage of cousins.

It may be objected that the evidence is extremely thin on which to try to correlate the emotional *orientation of infancy* with that of the primitive endogamous system. In fact it is impossible to prove this correlation in our attempt to get a true perspective. It is, nevertheless, very useful and as a working hypothesis it coincides with the proved experience of psychological research. It is as if the emotional orientation of the infant is essentially endogamous up to a period of one to three years, at the end of which recapitulatory phase the Mosaic taboo or its equivalent operates unconsciously and automatically to repress the incest motive. All the world over the incest motive is regarded with horror, because of the primitive taboo under which it has racially been placed, and this taboo also seems to be an object of individual recapitulation.

Psychologists are aware of the prevalence of this incest motive in the emotional lives of their patients. Freud has called it the "nuclear complex of neurosis." It is in fact probably the most important primary motive, but it requires considerable amplification from the simple conception of sexual incest before we can see it in correct perspective. There is no doubt of the recapitulation of the sexual factor in infancy, in spite of the absence of physiological sexual development. Any intimate and detailed experience of the psychology of patients will easily demonstrate this to be the case, in spite of the initial presence of a "resistance," due to the incest taboo, on the part of the investigator. The experience of the infant is so intimately associated with the mother that the pull of the maternal apron-strings remains the greatest problem operating against individual emotional development.

The name which has been given by Freud to the incest motive is, in the case of the male, the "Œdipus complex" and in the case of the female the "Electra complex." The story of Œdipus is one of the Greek myths, and it has already been mentioned in Lecture II. that myths are derived from unconscious emotional sources.

Œdipus was the son of Laius, King of Thebes, and Jocasta, his wife. His father, having learnt from an oracle that he was doomed to perish at the hands of his son, exposed Œdipus on Mount Cythaeron immediately after his birth, with the object of killing him. The child was found, however, by a shepherd in the service of the King of Crete, and was taken to the King's palace where he was reared by him as his own child. When Œdipus grew up the prophesy of the oracle was fulfilled, because in a scuffle he slew his father without recognising him.

In the Kingdom of Thebes there was a celebrated sphinx who put a riddle to every Theban who passed and whoever was unable to solve it was killed by the monster. Œdipus solved the riddle and as a reward became the husband of his mother, Jocasta, by whom he had several children. When Œdipus discovered the guilty nature of his alliance he put out his eyes and Jocasta hanged herself.

The choice of Electra as the feminine counterpart of Œdipus is due to the legend that she avenged the death of her father, Agamemnon, by assisting in the slaying of her mother, Clytemnestra. The case mentioned in Lecture II. of the girl who stated that she had been raped by her father is an excellent example of the Electra motive, as was shown in her attitude towards her mother and frequent occurrences of death wishes in which her mother figured.

The following is one of many cases which illustrate the Œdipus motive.

CASE M.—Male, unmarried, aged 24, professional musician. *Complaint:* Homosexuality with cough fetishism, self-consciousness, insomnia, depression, and suicidal feelings. *Family history:* His grandfather was an alcoholic. The patient had one sister 10 years older than himself.

Physical state: Nothing of importance.

History: The description of the fetishism was as follows. Hearing a cough of a definite character in certain individuals was the strongest sexual stimulus which he experienced. The person afflicted with the cough had to be of a rather rough working-class type and about the age of 25. If he heard a cough of a desirable kind he would follow it wherever the owner might be going in the hope that the cough would work up to a paroxysm, which would provide him with the crisis of his own sexual excitement. He stated that the man must be healthy and handsome with a large mouth and thickish lips, and that it was most important that the mouth should *not* be covered during the paroxysm of the coughing.

His mother had died when he was 21, and he stated that he had never got over it. He *traced the attractiveness of coughing back to the fact that up to the time when he was about 7 his mother had always had a severe cough.* He was most devoted to his mother and said that his life had always centred around her and that, as a child, he had "yelled if she went out until she came back." He stated that he loved kissing his mother and all the physical things that one does with one's mother, and he had had *many phantasies of intimacy of various degrees with her.* As he grew up he said that he had never found anything to take the place of what he had had in childhood from his mother. He *had no use for girls of his own age* but got on well with elderly women. He stated particularly that he had never felt any protective love for anyone, but only love of being protected.

When he was about 8 he came to actually dislike his mother's cough, but from that period he always became *attracted to people of his own sex, in whom a cough became* the focus of his sexual gratification. A man of about 40 years of age, however, with a cough gave him an intense feeling of nausea and fear.

With regard to his father, he said that he had never got on with him and had always been afraid of him. His father had a rather violent temper and he felt that his father ill-treated his mother. As a small child, in the mornings he used to try to get into their bedroom, and remembered the satisfaction of being in bed with his mother, especially if she had her back turned towards her husband. He said that he never lost an indefinable feeling of grudge against his father because of the way he had treated his wife. "It would not worry me" he said, "if I never saw my father again." With regard to his sister, he said, "I always feel I should be more fond of my sister if I did not feel I grudged her her place in my mother's affection." He could never tolerate the thought of growing up, and said that if anybody said "be a man," it made him ill with disgust.

He had a dream during his treatment: "I seemed to be in school but it was not exactly a school. It was either a hospital or a prison, in which I had to attend some lectures, but I found myself in bed under treatment. Near my bed there was a coffin in which I was told was my mother's body, from which my father's brother was going to take something out and give it to me. I was told it was some kind of material of evacuation which I should have to take into the lavatory. I felt the whole thing was ghastly, awful, and I said that I could not possibly do it, but I was told I must." He had no idea at first what had to be taken from his mother's body, and it was suggested after a while that he should draw what came into his mind. When he started to draw he was quite uncertain, but eventually produced the accompanying diagram, the significance of which would seem to be apparent, although he did not at first recognise what he had drawn.

He stated that he was quite sure he did not want any sort of cure, but only that things might be just as they were without any resultant dissatisfaction. When he realised the sexual and childish nature of his attitude towards his mother he accepted it freely and consciously. He said "I know it is perfectly true that I would like to have intercourse with my mother better than anything else in the world," but the acceptance of such an attitude in consciousness is very unusual. (The cough fetishism is an excellent example of a "complex" due to a "transferred affect.")

THE PATRIARCHAL SYSTEM.

Another aspect of primitive family life, which is important from the recapitulatory standpoint, is to be found in the "patriarchal system." The primitive tribal unit was held together by the tribal chief or patriarch, who was in a very real sense the head and owner of the tribal family. The patriarch possessed supreme rights over the members and property of the tribe and held his sway until such time as he was no longer able to maintain it. It is easy to imagine that his authority was maintained only in the face of considerable resistance on the part of certain stronger and younger members of the tribe. As the patriarch grew old and feeble, the power of his rule inevitably lessened and the criticism of those younger members who wished to take his place grew stronger. Eventually, either the patriarch died or was removed, and after a certain amount of quarrelling amongst the rival sons for the leadership of the tribe a new patriarch was installed in his stead.

The two outstanding points are first of all the rivalry between the patriarchal head and his younger tribal competitors, and secondly, the rivalry amongst those who wish to become the patriarch in his stead.

This conception of a *recapitulation of unconscious rivalry* adds to our knowledge and understanding of adolescent development. On the one hand stands the father, with the knowledge and power acquired through the status of his years. On the other, the growing sons whose developing urge towards the fulfilment of their lives leads them to regard the father with criticism and disapproval. It is important to look deeper than the levels of conscious rationalisation and superficial adaptation. Beneath this there is an underlying rivalry due to recapitulation of a primitive patriarchal system, deeply seated in the emotional lives of fathers and sons. It is in consequence of this that the father is liable to behave disparagingly towards the groping omniscience of adolescence. The other side of the picture is even more apparent, the son's intolerance of paternal authority and what he feels to be his prejudiced conservatism. It is not always that the rivalry breaks out into conscious conflict, but very frequently this recapitulation of primitive emotions is the cause of overt domestic quarrels.

The older generation needs to be conscious of this underlying tendency to regard the rising generation as rivals, to be held down and disparaged. Similarly, the younger generation need to be conscious of their underlying feeling that only the young know what they are talking about. The rivalry and mutual disparagement is very real and because it is unconscious it may be very dangerous. The patriarchal head of the family belongs by no means always to the remote past. His prototype ruled many Victorian families, against which the present generation is reacting, as the pendulum swings with a sometimes excessive freedom. If it is possible to detach ourselves from processes of unconscious recapitulation, we can discover virtues and feelings of sympathy both in father and in growing son, in die-hard Tory, and in hot-headed "left winger."

The passage of years and the acquiring of experience may add to our wisdom, but unfortunately this is not necessarily the case. A lifetime is but a small space in which to arrive at ultimate goals and whole-hearted wisdom, but it is nevertheless the only measure of our span. We are inclined to regard the sum of our own experience as ultimate and objective wisdom, whereas it is no more than an incomplete total of our prejudices. Both the virtue and the vice of adolescence lies in its assumption of omnipotence and omniscience. Whatever the patriarch may feel, his is only the past and to his sons he must be content to leave the future. Whatever the sons may feel, they must eventually recognise that with the passing of the years they will become not much different from their fathers. The patriarchs were great rulers, but patriarchs are liable to fail as educators of the next generation if they rule too strongly.

There is another characteristic of adolescence which may be noted at this point. It is a characteristic feature of the living organism, that it tends to react in the opposite direction to that in which it is pushed. It develops the opposing corrective to the forces which act upon it. Growing lives cannot be pushed or driven for very long without developing an emotional attitude of corrective rebellion. The patriarchal system can be maintained so long as growth remains subjugated, but it is very difficult to maintain the yoke. The stronger the patriarchal suppression the more intense will be the ultimate rebellious upheaval. A successful patriarchal system will either produce sterility or revulsion, whether it be in the nation or the more limited environment of the family.

It must be borne in mind that phenomena of recapitulation are largely independent of individual experience, although they may be modified or exaggerated by it. Of this point the following is an illustrative case, because the father was not obviously of the stern patriarchal type.

CASE N.—Boy, unmarried, aged 20. Eldest son, two younger brothers, two younger sisters. *Family history:* Good, but showed a difficult combination of optimistic, subjective, artistic strain on his mother's side and a pessimistic, abstract, legal type of mind on his father's. *Physical health:* Good.

History: The boy had always been rather difficult and eccentric. He had gone at the age of 8 to a boarding school and at the age of 14 to a public school, but had never been very happy or friendly except with boys who, like himself, found it difficult to fit in. At school he had shown more intelligence than the average but it had always been applied on strongly individualistic lines. He was particularly keen on mechanical contrivances and inventions and on amassing encyclopædic knowledge of doubtful practical utility. He was a destructive critic who was never satisfied with the existing order of things, or with such educational and social opportunities as came his way.

At home he never got on with his family and was regarded as a thorn in the domestic flesh, especially by his father. His father was shy, nervous, and retiring, and had brought up his family on the principle of letting them take care of themselves, except for certain terrifying injunctions which he frequently tried to impose on them, such as the statement that drinking hot tea induced cancer, and the general belief that young people never knew what they were talking about.

When the boy left school he went from one job to another, never staying anywhere longer than a few months because it had not afforded him sufficient opportunity to fulfil his egotism and because of his destructive criticism of the system in which he found himself. He combined curiosity and hot temper to a remarkable degree, with the result that he got himself into trouble with his superiors, and was finally referred to a doctor, who advised that he should be occupied with nothing more stimulating or responsible than digging in his father's garden. This he proceeded to do with growing irritation for 18 months, trying his hardest to exercise his inventive capacity by numerous ambitious and unpractical schemes, while his political opinions became progressively "left-wing." Finally, he could bear it no longer and wrote an ultimatum to his father to the effect that he wished to disown him, that his meals were to be served apart, and if his father interfered with him in any way he was not to be considered responsible for his behaviour. Upon the strength of this evidence the boy was certified, and for four months in a mental hospital his behaviour was exemplary.

He then came under analytical treatment and it was easy to understand that his intense enthusiasm for Communism was a defence for his unexpressed egotism. He was an intense propagandist, utterly intolerant of convention, whether national, religious, or domestic. Communism was the only outlet for his egotism and was adopted passionately and uncritically. His psychology was that of the complete rebel, but it was as dogmatic, intolerant, and authoritative as that of any dictatorial patriarch. His dreams were often of being on a high place such as a rock or tower and being attacked from behind by an elderly man who was trying to push him down to his destruction.

He had no sex life and no interest in girls, nor indeed in anything other than of an entirely material or scientific kind. His system of philosophy was inflexibly rationalised but it was in fact only symptomatic. In its dependence upon unconscious emotional sources it was as unscientific as the most emotional type of evangelical hysteria, in spite of his own belief to the contrary.

BECONTREE HEALTH CENTRE.—Brigadier-General R. B. Colvin, Lord Lieutenant of Essex, recently opened a health centre in association with the King George Hospital, Ilford. It provides for the urban district of Dagenham an out-patient department for consultation and treatment, and also houses the Infants' Welfare Clinic of the local authority. The building has cost £7200. In a speech at the opening ceremony Sir Cecil Levita, a former chairman of the London County Council, expressed the opinion that it would be better and more economical for the county councils to make block grants to the existing voluntary hospitals for the discharge of the health services which they themselves are bound to provide rather than to erect their own hospitals.

SPECIAL ARTICLES

SMALL-POX MAJOR AND MINOR.

A NOTE on various designations of small-pox and their epidemiological and prophylactic significance, prepared by Dr. Ricardo Jorge, was presented to the Permanent Committee of the Office International d'Hygiène Publique at its session of May, 1930, and having been approved by this Committee appears as an appendix to the further report[1] of the Rolleston Committee on Vaccination. In classical medicine, Dr. Jorge writes, a precise "system" of variola had been elaborated in the past which was so clear and impressive as to leave little to be desired. Based on obvious and well-marked external characteristics, this system became the current medical coin. Moreover, variola being a very common complaint, the general public itself created very similar categories, and in different countries baptised them with expressive and picturesque common names.

A Secession from the Orthodox.

The clinical variations implied in this "system" of variola governed diagnosis and prognosis without in any way disturbing the basic unity of the disease variola, or small-pox—a unity for which the facts of epidemiological control afforded a sufficient guarantee. With each epidemic outbreak, provided it was sufficiently extensive and severe, one saw unfolded the whole film of the varieties of variola, a gamut ranging from the most innocuous of abortive forms to severest confluent and hæmorrhagic types. All the links of the chain were firmly connected one to the other as they showed themselves interchangeable and reversible—being merely variable results of the same contagion.

Into this well ordered kingdom with precise and clearly marked boundaries, there appeared one day (well within our memory, during the present quarter of the present century) signs of secession from the orthodox. It had been noticed that a sequence of epidemics, sometimes great in number and wide in their distribution, were not conforming exactly to the established formulas of variola. Were they local, or accidental, or episodic anomalies? They had not this appearance. Discovered successively in America, Africa, and Australia, and there thought of as exotic, they presently came also to crop up in Europe itself in a way which demanded notice. To the new and troublesome variety of variola thus appearing in so many quarters all sorts of names were given; some of them invented on the usual lines of medical vocabulary, others of popular origin: variola minor, variola-varicella, para-variola, mild small-pox, white-pox, milk-pox, amaas, alastrim, &c.

All these variants, differentiated in time and geographically, came ultimately to appear identical and synonymous, and to produce a united front. Battle was joined between the two domains, a duel more passionate than is usually seen in the peaceful fields of modern medicine. Is there one variola only, or are there two variolas? This was the crux, and in the course of the contest over it, as so often happens, discussion turned to confusion. A problem well expounded is already half solved, but in this case the question for debate is too often badly stated. Words are used to which different meanings are attached, and misunderstandings become inevitable. Is it possible to bring order into the matter, if only to fix the significance and value of the terminology in current use?

If we were concerned with an unimportant disease, the task would not be worth so much expenditure of energy, but small-pox is a dangerous pestilence and a pestilence dear to the heart of preventive medicine which has found out how to subdue it and which is unwilling to admit anything that can hamper or obscure the efficiency of its prophylaxis or that can dim the brightness of its achievements. Strong sentiment animates the discussion; the possibility of weakening prophylaxis. Here, however, there is a point to be made clear; to assert that the question of prophylaxis remains outside the question of ontology, that anti-variola defence keeps its position safe and sound, and that the conception of alastrim does not take away from the accepted authority on which the strict application of measures necessary to prevent the ravages of variola is based.

Two International Texts.

There are two official international texts to consider which are concerned with variola—the Internationa Sanitary Convention of 1926, and the Convention of the List of Causes of Death, 1929.

The first text (the International Sanitary Convention deals with variola. It does not know "alastrim" or mentio it. The second text, however, expressly separates variol minor (alastrim) and variola major. Are these two text incompatible therefore? By no means; no such discordance did or could have entered into the intention of thei authors. In the International List as adopted there is onl one *main heading or rubric—Variola. Variola minor* an variola major are two sub-headings or sub-rubrics. I inserting them it was intended to provide for the possibilit of preparing statistical data on the frequency and appearance of these two varieties, whose existence it is impossib to disregard.

The International Sanitary Convention, on the oth hand, has only kept to the use of the generic term variol it being understood that, whichever or whatever form may take, it is a disease liable to compulsory notificati and covered by the several requirements laid down for in the Convention. There is no other admissible interpretation. It has been suspected that by attaching the lab "mild small-pox" or "alastrim" to an epidemic, use being made of a subterfuge or euphemism by which to clo true small-pox. The word camouflage even has been used in this connexion. Thus in times past cholera, still more dreaded, was hidden under the mantle of "cholerine."

But we are not aware that evidence of this contention has been established or that its actual existence has been suspected. The term variola minor does not usurp the place of variola major. On the contrary, the former is often *substituted for the latter because the designation alastrim* is not an officially accepted term in many countries. Varicella, which everyone distinguishes from variola, itself not seldom serves to disguise the latter, not intentionally, it is true, but because of errors of diagnosis made by practitioners to whom variola is no longer familiar. Cases of variola or even of alastrim, passing undetected under the innocent name of varicella, have been the source of formidable epidemics. On the occasion of the recent outbreak in Holland, though considered by the sanitary authorities at the beginning of its course to be alastrim, the customary compulsory notification was immediately put into force, and international appraisement with all the necessary details followed in due course.

In any event an invasion of alastrim, even of the mildest variety, is by no means to be desired, and if it assumes large proportions, as has happened at Guadeloupe, at San Miguel, and elsewhere, the illness produced causes considerable damage and economic loss. Moreover, fatalities, however few, cannot be regarded as of no account. As far as local preventive measures are concerned, alastrim is not exempt from obligatory notification by medical practitioners *nor in principle from the measures* calculated to check its spread; particularly so since it is difficult and imprudent to be dogmatic, when confronted with the early cases, as to what kind of variola one is dealing with. Recent legislation in Holland recognises the duality, but without excluding the application to variola minor of strict precautions necessary for the control of variola major.

---

[1] See THE LANCET, Jan. 10th, p. 85.

As in all epidemic disease, the practical question lies in the degree and dexterity of the necessary sanitary control. The dissemblance of alastrim from orthodox small-pox, due to the benign nature it sometimes assumes, often puts a check on the exercise of the whole forces of prophylaxis. If small-pox has drawn all these forces of prophylaxis into combat against it, it is simply because it is extremely dangerous. The salutary fear of its ravages becomes enfeebled and almost disappears in the eyes of the public when in the face of outbreaks of almost nonfatal mild small-pox.

Meaning of the New Terms.

We may now turn to the meaning which should be attached to the new terms which have been introduced into the variological vocabulary and consider their legitimate effect in regard to older designations. In this connexion it is merely a triviality to say that variola is "benign" or "severe"; in all infections there are variations in severity within very wide limits. So also to say that an epidemic of variola is benign or severe is merely to state an impression of the whole or that there has been a definite statistical finding—for instance, that there has been an excess of mild cases over the usual average.

From the earliest times we have known of the existence of epidemics of small-pox that were very severe and others that were much less severe; those which Sydenham called "*variolæ mitiores.*" Why, then, it may be asked, should we now create a new and separate category—that of variola minor or "alastrim"? Is not this "alastrim" only a new and useless name for the old term "varioloid," which denoted a clinical form of the disease which was modified, mitigated or abortive? The reply is that it is an error to adopt or compare these two varieties and to regard them as synonymous. The question implies a misinterpretation which should first be eliminated from the discussion altogether. Everyone recognises the inappropriateness of the term "varioloid"—an unfortunate term introduced by Thompson in 1820. Its use should be discontinued, but our conservative terminology holds on to it and persists in using it in the ordinary language of medicine, which we must admit not to be sufficiently disciplined. It is well to consider how "varioloid" has acquired the favour which it has so little merited. When the diffusion of the Jennerian method had made its weight felt on the evolution of epidemics, large numbers of cases occurred in which the disease and the rash were only a faint outline of the features of true variola. It was found that vaccinated subjects could be attacked with a harmless abortive type of small-pox which was only the shadow of its parent; hence "varioloid." The people of different countries, as is their custom for any infections which begin alarmingly but quickly clear up, used picturesque metaphors to describe what was in their eyes no more than the caricature of a disease—the same has happened for variola minor.

The term "varioloid" was itself badly chosen, as it entailed two errors. First, "varioloid" is not a species different from ordinary variola, for the two are interchangeable, variola giving rise to varioloid and vice versa. Next, varioloid is not invariably a degenerated form due to vaccination and peculiar to the vaccinated. It is to be found, although much less commonly, among the unvaccinated and it had already been observed in epidemics which had occurred prior to Jenner's discovery. Varioloid may present a definite clinical form, but it is not an epidemic variety, and it would be incongruous to talk of epidemics of varioloid. The total number of cases of varioloid in a particular outbreak may be high, but once they have been separated, the cases of ordinary type, more or less severe, which remain, are sufficient to characterise the epidemic.

There are the following differences between "varioloid" and alastrim. In "varioloid," particularly amongst the vaccinated, the exanthematic elements abort when once they have appeared; the papule subsides, the vesicle dries up, only a few scattered elements reach pustulation, and even then the little pustule dries up as soon as it is formed. Furthermore there is no secondary fever and no pitting, or only very rarely so. In alastrim there are many cases which are indistinguishable from varioloid, but there are others in which the disease assumes all the known forms of variola from discrete to confluent, and one may even add the hæmorrhagic, but without departing from the rule of benignity. This forms the characteristic of variola minor. In variola major the prognosis and the issue are determined by the intensity of the rash, and the severity of the case is graded according to its exanthematic scale, discrete, coherent and confluent. Alastrim often displays a magnificent eruption, generalised or localised, coherent or even confluent. But in spite of this the patient does not succumb to suppurative fever, which is most rare; he feels comfortable and well in himself; in good condition, as if he were but slightly indisposed, or not ill at all. Toxic infection, in fact, is reduced to a minimum.

It is this individual paradox, leading up to the collective paradox, of progress which is nearly always favourable and is insignificant in the matter of fatality, that gives to alastrim its right to a separate place. It is no mere matter of a clinical type, as is the case with varioloid, but of a noso-epidemiological type, since it has maintained these characteristics throughout the course of long and extensive epidemics occurring, it is important to note, among populations which have not had the benefits of vaccination. One epidemic of it has followed another in the same locality for a considerable series of years, going on always in the same way. And when these epidemics move away from the locality and spread elsewhere, they keep the same character. They sometimes co-exist with variola without intermingling.

An Example.

This is a fact which seems to be settled by experience of the past and by present happenings. If, for example, one takes any recent record of epidemiological movements and examines the incidence of small-pox throughout the world, one will find such examples as the following:—

England and Wales.—Week ending April 12th, 423 cases, two deaths provisionally attributed to small-pox; for the year 1929, 10,940 cases, 29 deaths, fatality 0·26 per cent.

United States.—For the year 1927, 34,327 cases, 163 deaths, fatality 0·47 per cent.

Canada.—For the year 1929, 1952 cases, five deaths, fatality 0·25 per cent.

Belgian Congo.—For the year 1929, 2433 cases, 60 deaths, fatality 2·16 per cent.

and by contrast:—

Bombay.—Week ending April 19th, 114 cases, 78 deaths, fatality 68·4 per cent.; for the year 1929, 2013 cases, 1068 deaths, fatality 53·05 per cent.

Pondicherry.—For the year 1929, 500 cases, 393 deaths, fatality 78·0 per cent.

British India.—For the year 1929, 148,106 cases, 34,393 deaths, fatality 23·2 per cent.

The contrast shown by this series of figures is striking. They are the two different orders of fact which it has been intended to express by *variola major* and *variola minor*. No more than this, and no prejudice being imported by this distinction into prophylaxis or into clinical judgment. Epidemiology alone is taken into account. It is epidemiology which requires us to separate the two epidemic progressions as far as possible and which asks us, by systematic inquiry regarding cases and through statistical methods, to increase our knowledge of the manner in which this paradoxical phenomenon comes about.

A Fixed and Stable Mutation.

There is one point the capital importance of which must be insisted upon; the question whether the two varieties are interchangeable, and whether an epidemic of ordinary variola major can result from alastrim or variola minor, and vice versa; since up to the present they have shown themselves immiscible, each keeping its own independence. Experimental pathology has lately provided valuable contributions to our knowledge, and although the problem is not yet entirely solved, there is reason to believe, from animal experiments, that the two viruses are of the same nature, but that in the case of alastrim in man the toxic-infectious power of the virus has been greatly reduced. Vaccine lymph is also a derivative of variola virus; vaccine can be made by starting with variola virus, but one cannot reconstitute smallpox from such a vaccine; there is no reversibility. If the alastrim virus, as everything seems to indicate, represents a fixed and stable mutation of that of ordinary variola, we do not yet know the conditions which determine that mutation and cannot therefore say on experimental grounds whether they are or are not reversible. But, Dr. Jorge concludes, we must repeat that, judging by epidemiological observations, the two varieties do not seem to be interchangeable.

PARIS.

(FROM OUR OWN CORRESPONDENTS.)

THE INTERNATIONAL UNION OF DOCTORS.

HOUSED in Paris, at 95 Rue du Cherche-Midi, the International Union of Doctors or *l'Association professionnelle internationale des médecins* carries on the activities of a trade-union rather than of a scientific body. It is a live wire, largely owing to the enterprise and activity of its Secretary-General, Dr. Fernand Decourt. It was established in July, 1926, after a year's preparatory work by a provisional committee, and according to its statutes its aims are to form a central clearing house of information and to be a link between national groups of doctors so that each may profit from the experiences of the rest in the study of the numerous professional problems affecting their private and social lives. Strictly scientific subjects are not dealt with, or only in so far as they present sociological problems. Since the secretariat began work in Jan., 1927, as many as 16 different international inquiries have been set on foot, among the most important being those about sickness insurance, specialising in medicine, the illegal practice of medicine, administrative measures against maternal mortality, and the antituberculosis and antisyphilitic campaigns. Reports on these inquiries are published in the Union's quarterly journal—*La revue internationale de médecine professionnelle et sociale*—which is published in French, but which has many readers abroad. The organisation of the Union is most simple: Each country adhering to the Union, be it as small as Luxembourg, with only a few hundred members, or as large as the United States, with some 72,000 doctors, appoints a national delegate who is the only official connecting link between his country and the Union. He is usually the president or secretary-general of his national medical association. The general council is composed of these delegates, and it meets once a year on four successive days in one of the European capitals. It met in Paris last year, and this year it will meet in Budapest. The general council nominates an executive committee of ten members to deal with current and urgent affairs. There is no president. The treasurer is a Dutchman. Beginning with a modest membership of six, the Union now includes 31 countries.

OUR DAILY BREAD IN FRANCE.

Just before Christmas the *Confédération des syndicats médicaux français* held its general annual assembly and dealt with various matters of medico-social importance. The second subject on the agenda was: Fraud in the Making of Flour and Bread. The author of the report on this subject was Dr. M. Lenglet, the representative of the *Confédération* on the *Conseil supérieur de l'hygiène.* He traced the evolution of flour and bread making during the past 50 years, showing how difficult the task of making bread has become owing to the changes wrought in the flour. Going through the various processes of flour and bread making, he must have ended by giving the most impressionable among his audience the conviction that in its ultimate metamorphosis the loaf in France to-day would be more accurately described as a chemist's shop than as the staff of life straight from the mill. It would surely, however, be fairer to use the term adulteration than fraud in connexion with the many different chemical processes which in the course of years have been evolved by the two great industries concerned. Be that as it may, Dr. Lenglet's report was received with applause, and a resolution was adopted urging the Ministry of Health to solve this problem at once, to take as a matter of urgency all the necessary measures, with severe penalties, for dealing with the frauds in bread-making which may have serious effects on the health of the whole nation. The *Confédération* further gave its representative the mandate to protest on behalf of the medical profession before the *Conseil supérieur* against the granting of licences which entail the employment in bread making of substances injurious to health. The vigorous wording of this resolution, the emphatic comments of the chairman of the meeting, Dr. Dibos, and the sympathetic applause of the audience should all serve to strengthen Dr. Lenglet's hands in the further pursuit of his objective.

LECTURES ON TROPICAL MEDICINE IN PARIS.

The forthcoming Colonial Exhibition, so admirably advertised by the new French postage stamps, will include a course of lectures on tropical medicine between July 22nd and 31st. The programme is remarkably comprehensive. Infant welfare among the natives, tropical diseases including syphilis, social hygiene and welfare work, drinking water, diseases transmitted by animals, colonial pharmacology and, at the end, sanitary aviation with demonstration of aeroplanes. Foreigners as well as Frenchmen will be allowed to take part in the ensuing discussions, and the fee of Fr.100 (Fr.50 for relations and students) will incidentally give participants in this course the substantial benefits accorded to visitors by travel agencies and restaurants within the exhibition. Further information can be obtained about these lectures from the *Secrétariat général des journées coloniales*, 112 Bd. Haussmann, Paris.

LECTURES IN ENGLISH TO MEDICAL VISITORS TO PARIS.

Another course of lectures has been arranged in response to letters on this subject addressed by Prof. Dubé of Montreal to Prof. Roussy and Prof. Sergent. They will be held under the auspices of the *Association pour le développement des relations médicales avec l'étranger* in July. The sponsors of this course will be Profs. Sergent, Gosser, Chevassu, Sorrel, Claude, Morax, Lemaitre, Ledoux-Lebard, and Roussy. The subjects will be diseases of the lungs, surgery of the digestive tract and liver, urology, orthopædics, psychiatry, ophthalmology, oto-rhino-laryngology, radiology, and radium treatment.

PENALTIES FOR THE TYPHOID EPIDEMIC IN LYON.

Some two years ago a suburb of Lyon suffered from a serious outbreak of typhoid fever for which the local water company and its director were held responsible. After a lengthy trial they were condemned last June by the *Tribunal correctionnel* which sentenced the director to a year's conditional imprisonment (*avec sursis*) and the company to material damages for the benefit of its victims. The company appealed against this verdict, and the Court of Appeal of Lyon has now passed judgment; so far from mitigating any of the sentences, it has increased most of the damages awarded against the company to the sufferers.

MENTAL SPECIALIST INJURED BY A PATIENT.

Dr. Raviart, professor of mental diseases at the faculty of Lille, has been badly wounded by a bullet in the lumbar region by a lady who happens to be the wife of a physician. She had shown for a long time definite signs of insanity and had been certificated by another physician and placed in a mental institution 18 months ago, at a time when Dr. Raviart was attending a congress in Spain. The very day after his return the lady escaped from the institution, but nevertheless continued to regard Dr. Raviart as the cause of her incarceration. The accident is one of a kind all too frequent in France where mental specialists constantly live in danger of their lives.

LATENT EPILEPSY IN SCHOOL-CHILDREN.

Dr. Gilbert Robin, who specialises in Paris on the mental diseases of children, made a communication to the Academy of Medicine on the relation of school inhibition to latent epilepsy. Dr. Robin considers that when a young scholar shows marked hesitation in answering a question and blunders as if he were just out of a dream the teacher should think of epilepsy. The clinical picture is characteristic. The child does not show emotion; he stands still with a peculiar way of looking, either fixedly or with wandering eyes. Investigation shows that the child fails to respond, not because he does not know the answer, but because he has nothing to tell, his brain being empty at the time. Sometimes amnesia follows. Other stigmata of epilepsy may be found; one of these is a permanent slow cerebration. The importance of differentiation from simple emotional disturbance lies in the fact that for minor epilepsy much improvement may be expected from luminal combined with small doses of arsphenamine, mercury, or bismuth, whether evidence of syphilis is present or not.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

DIET PROBLEMS.

Prof. Carl von Noorden recently read a paper before the Berlin Society for Internal Medicine on some of the problems of diet. Certain reformers, he said, think that human blood is too acid and must be made alkaline by diet. Actually the reaction of the blood is constant; on the other hand, the reaction of the tissues may be altered to some extent, for it depends on the mineral content of the cells in which the surplus of minerals introduced from the diet is stored. Food can produce mineralisation or demineralisation, but it has not yet been ascertained whether the clinical effect of certain dietetic methods is based on this action. Every forced diet—for instance, war diet, prisoners' diet, or milk diet—produces a certain amount of demineralisation. As to common salt, it is true that we consume too much; instead of the usual quantity of 15 g. daily, 8 to 10 g. are sufficient. The use of a great quantity of salt is a sign that the food is badly prepared, the salt concealing the bad taste. A diet without common salt does not exist, and the so-called salt-free diet is merely one to which no salt is added. The Gerson diet recommended for tuberculosis as salt-free contains 6 or 7 g. daily. Speaking on vegetarianism Prof. von Noorden said he thought that 60 to 90 g. of nitrogen, which is the average quantity in ordinary food, is not excessive. A diet with little or no albumin is, of course, very useful in certain heart and renal diseases, but in nervous patients it is advantageous only by suggestion. An ordinary diet contains enough vitamins; the modern overestimation of vitamins by the public has almost become a mania, and has led to vitamin intoxication in certain cases. Raw food is poor in fat and is useful in combating adiposity and arthritis. A starvation diet is, as a rule, unnecessary; in chronic cases it is enough to prescribe days of partial abstinence once or twice a week, and allow the patients more liberal fare for the rest of the time.

MANSLAUGHTER BY NEGLIGENCE.

An unqualified practitioner treated a patient who complained of pain in the chest, and dissuaded him from consulting a medical man. Hæmoptysis and high fever developed, but he continued to treat the patient on his own responsibility. On the fourth day the family introduced a medical man, who diagnosed severe pneumonia and pleurisy, and two days later the patient died. The unqualified practitioner was prosecuted for manslaughter by gross negligence, and sentenced by the local court to three months' imprisonment. According to the verdict his negligence consisted in having undertaken the case without having any medical training. A medical expert witness testified that the life might have been saved if a stimulating remedy had been prescribed at the beginning of the illness. It was further considered negligence that the patient was dissuaded from consulting a qualified medical practitioner. On appeal the High Court confirmed the judgment. The accused pleaded that he had believed in the efficacy of his treatment, but the High Court said that this was not a sufficient excuse, and blamed him because he had not discovered the obvious worsening of the patient's condition. This judgment makes it clear that an unqualified person with no medical knowledge is liable to be punished if he undertakes to treat serious cases.

PERCAIN ANÆSTHESIA.

Dr. Widenhorn reports in the *Archiv für Klinische Chirurgie* the results obtained in 160 cases with percain anæsthesia. To combat the vasodilator effect of the drug 10 drops of a 0·1 per cent. solution of adrenalin were added to 100 c.cm. of the 0·1 per cent. solution of percain used for subcutaneous injection. Percain proved useful in rhino-laryngeal operations in a 1 per cent. solution, and excellent results were obtained in urological work where the urethra could be made anæsthetic by 10–12 c.cm. of a 0·15 or 0·25 per cent. solution (with three drops of 0·1 per cent. adrenalin for 100 c.cm.). For anæsthesia of the bladder 30 c.cm. were required to produce anæsthesia within five to ten minutes. In hæmorrhage of the bladder, rinsing with this solution has an anæsthetic and styptic effect. It is thus indicated in tenesmus, contracted bladder, hæmorrhagic cystitis, and vesical cancer. Percain must not be introduced directly into the circulation, because it produces a sudden decline of blood pressure and respiratory troubles. It is, therefore, not admissible for lumbar, paravertebral, or splanchnic anæsthesia. Its action is many times stronger than that of cocaine.

STORING OF RADIOGRAPHIC FILMS.

The German Röntgen Association discussed at their last meeting the question of the safe preservation of X ray films, for which they have published rules in conjunction with film producers, fire insurance companies, and fire brigade authorities. According to these rules, so-called safety films should be used instead of combustible celluloid films. The celluloid film is dangerous not only because it is inflammable, but also because in burning it develops poisonous gas, especially hydrocyanic acid. Only small quantities of film should be kept in laboratories or wards. The archives, which in big hospitals sometimes contain hundreds of thousands of films, must be kept in fireproof magazines, and these should be at a distance from the sick rooms and situated in the upper floor so that gas can escape.

PUBLIC HEALTH SERVICES

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1929 statistics of three counties, a county borough, and a rural district:—

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality in childbirth.
Aberdeen .. (110,127) extra burghal	20·3	13·3	0·92*	1·30	1·7	—	72†/—	—	2·4‡
Fife .. .. (110,797) extra-burghal	17·6	11·7	0·69	1·22	2·2	1·4	74/—	41	10·0
Ipswich .. (85,800)	16·7	12·2	0·93	1·58	2·2	1·8	53/30	—	2·8
Soke of Peterborough (51,220)	15·9	13·4	0·62	2·00	2·3	2·0	57/—	—	3·7
West Lancashire, R.D. (23,270)	13·6	12·0	0·66	1·50	2·1	1·4	63/—	—	3·1

Registered stillbirths per 100 live births: Ipswich 4·8, West Lancashire 3·1.

Notified stillbirths per 100 live births: Fife 4·8, Soke of Peterborough 1·9.

* In a population of 148,703, which includes all the ten burghs.

† In a population of 125,747, which excludes the burghs of Peterhead and Fraserburgh.

‡ From sepsis only in a population of 125,747.

County of Aberdeen.

Dr. Harry J. Rae's report shows that there are eight districts and that for tuberculosis, school and V.D. service the county scheme embraces ten burghs, for maternity and child welfare eight burghs, and for other public health services nine burghs. Up to the end of 1929 Peterhead had a separate medical officer of health. An important matter under consideration during the year was the concentration of isolation hospital accommodation. There are at present 12 such hospitals and their number has to be cut down. During 1929 the burghs had a lower birth-rate and infant mortality-rate but a higher death-rate than the districts. The percentage of illegitimate births in the eight districts grouped was 17·3, and in nine burghs grouped 10·1. During the last four years there has been a marked increase in the provision of new houses. Dr. Rae points out that the conservation of existing houses in rural areas is perhaps more important than the provision of new houses. The Housing (Rural Workers) Act, 1926, is, in his opinion, the only Housing Act that has tended to conserve rural housing and so prevent rural depopulation. Several districts have taken advantage of this Act. In 1927 there were 50 applications, in 1928 136, and in 1929 199. Of the 1929 applications, 102 came from the Deer district. Aberdeenshire has done better than most counties, but the erroneous impression has existed that the Act does not apply to burghs. However, in 1929 four applications came from Inverurie Burgh and one from Huntly. Dr. Rae hopes that this Act will be even more extensively used by the recently appointed district councils. As regards new housing schemes in villages the cost is frequently greatly increased by the need to provide an adequate water-supply and up-to-date sewage disposal.

Immunisation has given more satisfactory results against diphtheria than against scarlet fever. About 460 children were immunised against one or both during the year. There were 40 notifications of typhoid fever and 3 deaths; 28 of these occurred in the Deer district and were mostly associated with a village milk-supply. The whole of the dairyman's family was affected simultaneously and the milk-supply was stopped. An effort is made to provide hospital treatment for pneumonia in five hospitals. There were 442 cases notified and 82 received hospital treatment, apart from those treated in the Aberdeen voluntary hospitals. Domiciliary nursing is also supplied for pneumonia cases. Nursing services are provided by 38 associations, employing 39 nurses, of whom 34 are Queen's nurses. The associations are subsidised and the nurses undertake health duties for all the county schemes. They are not encouraged to act as midwives and only one district nurse in a sparsely populated area is registered as a midwife. It is estimated that ten additional district nurses are needed to cover the whole county. Several of them have motor-cars and motor-cycles. The V.D. scheme is a joint one with Aberdeen city, the north-eastern counties, and Zetland and Orkney. The new venereal cases in 1929 numbered 103. Those who failed to complete treatment numbered 13, as compared with 24 in 1925 and 20 in 1926. Dr. Rae refers to the weak point of the scheme—namely, the inability to secure continuity of treatment until cure is effected.

The veterinary inspector deals with the difficulties met with. The inspection season, when the cows are housed, only lasts from the middle of November until the end of April and much time is wasted in futile visits. In the Deer district during 1929 the roads were impassable for part of this short period. In any case a county of 2000 square miles cannot be dealt with by one inspector. Most of the dairy farms were visited once. The cows in milk inspected numbered nearly 10,000 and the dry cows nearly 2000. Among these, 22 were found with tuberculous udders and 39 with other forms of tuberculosis. It is pointed out that there are many unregistered dairy farms supplying villages in the case of which inspection is more needed than for the registered farms. Primitive customs also prevail in farms which produce butter.

> "Some have a special cream jar which is never washed, the inner surface of the jar showing a very uneven appearance caused by the series of rings formed by many hardened layers of solidified cream deposited on the jar. This jar and its condition is considered necessary for the 'ripening' of the cream."

In some cases the cream jar is kept in a not too clean kitchen, used as a family living-room and perhaps for sleeping purposes. The condition of the registered farms was maintained at a high level. Cow-keepers who adopt the practice of daily grooming and clipping of the hair never give it up. A large number feed twice a day only, with no decrease in the milk yield, and more farmers are adopting a ration combined with recording of the milk yield instead of the old unsatisfactory method of giving all the cows the same ration regardless of their yield.

County of Fife.

Dr. G. Pratt Yule shows that the county did not suffer excessively from the influenza epidemic. The death-rate of 11·7 compares with 11·2 in 1928 and 11·8 in 1927; while the infant mortality (74) compares with 81·9 for 1928 and 86·5 for 1927. The percentage of illegitimate births was 7·98, and Dr. Yule points out that every year approximately half the infant deaths are neonatal. Maternity and child welfare work is domiciliary at present, and Dr. Yule looks forward to the establishment of centres which can be used for school-children also. Child welfare work is one of the services transferred from small burghs to the county council under the Local Government Act, 1929, and the clinics in operation in some of these burghs will become available for surrounding landward areas. There is a clamant need for an adequate maternity service furnishing medical, nursing, and hospital supervision for the mother in pregnancy and childbirth and for mother and infant thereafter.

During the last two years there has been a slight check to the decline in the tuberculosis mortality. This decline began, evidently as the result of economic and social progress, years before the county council adopted special measures in 1912 and has continued steadily since that date. The work of the tuberculosis scheme is purely domiciliary. An effort is made to examine contacts, but occasionally a family of contacts is lost sight of after the death or removal of a cured patient from the register. The lack of an X ray apparatus is a handicap in the diagnosis of doubtful cases and entails admission to Glenlomond sanatorium for a short period of observation. It is customary for bone and joint cases to be taken to the general hospitals, whereas their treatment would be better carried out under sanatorium conditions. Increasing use is being made of the Housing (Rural Workers) Act, 1926, and the approved applications from the four districts numbered 121. Dr. Yule points out that, prior to the operation of this Act, nothing had been done or was even contemplated for the better housing of rural and agricultural workers, whose need was always obvious. He sincerely hopes that the Act will be renewed as otherwise, with the agricultural industry in its present state, rural housing will go from bad to worse.

Progress has been made with the enforcement of the dairy by-laws and the county veterinary surgeon inspected over 14,000 cows in the year. Those condemned under the Tuberculosis Order numbered 78 and included 18 suffering from tubercle of the udder.

Ipswich.

Dr. A. M. N. Pringle reports that the municipal maternity home of eight beds has become inadequate, and is to be extended. The enlarged home will have 17 beds. During 1929 167 cases were admitted, including 31 from outside areas. About 10 per cent. of the Ipswich mothers enter the home for confinement. Two-thirds of the confinements were conducted by the midwives and in one-third medical assistance was sought. Dr. Pringle gives particulars of twin pregnancies in Ipswich during the last nine years. The result of 58 male twin pregnancies was 101 live and 15 stillbirths; the result of 47 female twin pregnancies was 89 live and 5 stillbirths; the result of 56 mixed twin pregnancies was 98 live and 14 stillbirths. The percentage of still to live births was therefore 14·8, 5·6, and 14·3 in the respective groups. The 14 stillbirths in the third group were 7 male and 7 female. The percentage of stillbirths to live births for the whole series was 11·8, about three times the ordinary stillbirth-rate. A table shows how the age constitution of the population has been changing in recent years, with the diminution of the birth- and death-rates. Although more males are born than females, the higher male death-rate results in Ipswich in 1500 women to 1000 men over 70 and 2 women to 1 man over 80. In 1929 47 per cent. of the female deaths were at ages over 70 but only 36·6 of the male. The effect of the influenza epidemic was relatively slight in Ipswich. Dr. Pringle notes that the type of diphtheria was more severe and that mastoid disease was a frequent complication.

Soke of Peterborough.

Dr. C. Rolleston says that only once since 1907 has such a high death-rate been recorded—namely, in the influenza year of 1918. Pneumonia claimed more victims than ever—viz., 35. In Peterborough City 138 cases were notified and there were 24 deaths. Dr. Rolleston comments on the anomaly that there was no hospital accommodation for pneumonia, whereas hospital beds were occupied by 231 cases of mild small-pox and 98 cases of scarlet fever (of which three died). He recommends the provision of nurses for home treatment and the provision of beds in the local voluntary hospital, the Thorpe-road Institution, or in private nursing homes. Up to now no antenatal centres have been established in the Soke. Dr. Rolleston suggests that a consulting obstetrician should be engaged to visit one of the institutions just mentioned from time to time for the purpose. In 1928 the corporation of Peterborough considered a proposal to erect a small building for this purpose but the proposal was rejected. In tuberculosis Dr. Rolleston's experience leads him to emphasise that every method of diagnosis should be employed and that no case, however advanced, should be given up as hopeless. The present report contains notes of 23 cases treated by artificial pneumothorax since 1916. Seventeen of these persons are in good health and at work, three are in fair health, two are invalids, and one has died. The cases were all advanced ones and in many the tubercle bacilli in the sputum have disappeared. There was one death of an infant from pulmonary tuberculosis. The infant was not wasted, but constantly coughing and spitting and the sputum contained copious tubercle bacilli.

West Lancashire.

This rural district of 61,797 acres lies between the estuaries of the Ribble and the Mersey. It is sparsely populated and mainly agricultural. On the east it touches the Lancashire coalfield, where 114 of the residents work as colliers. Other industries are basket making and market gardening and there is one weaving mill. The areas adjoining Liverpool, Ormskirk, and Southport tend to become residential suburbs for the overflow population. There is no public water-supply but water mains are brought into the district by the water departments of seven neighbouring towns. The source of the water is wells sunk in the upper and middle Bunter beds, and the hardness of the water is very variable and erratic. A table shows that it may be anything from 7 to 33 degrees. In the township of Bispham there is no public supply available and the inhabitants depend on wells and stored roof water. In another district reclaimed from the sea, only roof water is available and the owner of the farms conveys water to his tenants when the rainwater supply fails. The cleaning of these drinking water tanks and the elimination of the dirt from the roofs does not receive adequate attention.

There are 15 townships in the district and the danger of being misled by statistics for small populations is illustrated by a table showing that in six of the townships there was no infant mortality—

whilst North Meols, a former fishing village, removed from the sea by a reclaimed tract, had an infant mortality-rate of 228. There is severe overcrowding in many parts of the area and several back-to-back houses need to be converted. A council scheme for new houses was to be put in hand in 1930. The description of the centrally situated isolation hospital shows that it is run on thoroughly up-to-date lines. It serves a total population of 32,000 and plans have been prepared for a new pavilion. There is no general hospital in the district.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 10TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 228 (last week 164); scarlet fever, 1649; diphtheria, 1263; enteric fever, 20; pneumonia, 1638; puerperal fever, 44; puerperal pyrexia, 114; cerebro-spinal fever, 26; acute poliomyelitis, 3; encephalitis lethargica, 13; dysentery, 19; ophthalmia neonatorum, 95. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 13th–14th was as follows: Small-pox, 215 under treatment, 3 under observation (last week 224 and 4 respectively); scarlet fever, 1608; diphtheria, 1971; enteric fever, 16; measles, 80; whooping-cough, 133; puerperal fever, 24 (plus 7 babies); encephalitis lethargica, 121; poliomyelitis, 1; "other diseases," 53. At St. Margaret's Hospital there were 22 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 77 (0) from measles, 8 (0) from scarlet fever, 21 (1) from whooping-cough, 32 (6) from diphtheria, 72 (19) from diarrhœa and enteritis under two years, and 101 (16) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London occurred at Liverpool. The same city reported 15 deaths from measles, Hull 12, Bristol 9, Birmingham 8, Newcastle-on-Tyne 6, West Bromwich and Sunderland each 5, and Gillingham 3 from the same disease. Liverpool and Manchester each reported 3 deaths from whooping-cough. Diphtheria claimed 5 victims at Liverpool, 2 each at Smethwick and Birkenhead. Diarrhœa was credited with 10 deaths at Liverpool, 5 at Manchester, 4 each at Birmingham and Sheffield. Of the 85 fatal cases of influenza outside London, 15 were reported from Liverpool, 10 from Birmingham, and 4 from Manchester.

The number of stillbirths notified during the week was 305 (corresponding to a rate of 43 per 1000 births), including 61 in London.

AN IMPORTED CASE OF PLAGUE.

The case of plague reported from the Port of Brist
in the return for the week ended Jan. 3rd was foun
on board the s.s. *Mariongo de Thermiotis* which le
Novorossisk (Black Sea) on Dec. 6th with a carg
of wheat, called at Zoulgoldak on the 7th and Andr
(Greece) on the 11th, and reached Avonmouth o
the 30th. The second engineer sickened on the 13
with fever and pain in the groin, his illness bei
recognised as bubonic plague on arrival at Avonmout
where he was removed to hospital. Only one rat w
caught on board and that showed no sign of plagu
The ship was fumigated and no further cases occurr

CORRESPONDENCE

BISMUTH FOR LUPUS ERYTHEMATOSUS.

To the Editor of THE LANCET.

SIR,—In an article which you published last week (p. 126) Dr. R. M. B. MacKenna mentions that he has not been able to find any record of the treatment of acute lupus erythematosus with bismuth. As I was responsible for the treatment in 1929 of a patient suffering from acute generalising lupus erythematosus with bismuth injections, the following particulars may be of interest:

The patient was first seen by me on August 15th, 1929. She appeared to be ill and had patches of inflammation on each malar prominence, the nose, the lobes of both ears, finger tips, and an oval patch on the tongue. She was advised to stay in bed and apply calamine lotion. On Sept. 12th bi-weekly injections of bisglucol were commenced. The patient appeared to improve slightly at first, but this treatment was discontinued after the ninth injection as the pulse-rate was increasing, the temperature rising, and she was losing weight rapidly. She died on Nov. 13th.

I may say that I have treated 14 cases of the localised variety of lupus erythematosus with intramuscular injections of bismuth since March, 1929, most of them with very gratifying results, and I believe this to be the method of choice in the treatment of the complaint.

I am, Sir, yours faithfully,
RUPERT HALLAM,
Hon. Physician in Charge of the Skin Department,
Jan. 17th, 1931. Royal Infirmary, Sheffield.

MOTIVES AND MECHANISMS OF THE MIND.

To the Editor of THE LANCET.

SIR,—As you say editorially (1931, p. 29) the medical profession is being forced, partly from without, to consider psychology more intensively. Whether we will it or not, the public will have psychology and even children begin to talk of "complexes." Lead
ship is needed, but do we want the noble professi
of medicine to pander to the libidinous tendencies
this generation?

Slang terms, or "pictographic expressions" bei
to the fore, I may justifiably say that this arti
(THE LANCET, Jan. 17th, p. 147) "gets
goat." This phrase, like the nursery rhymes
those sinks of sexual allusion when psychologica
analysed (p. 149), is pregnant with meaning
goat, Pan, maenads, saturnalia. What enorm
will emerge from the analysis of Jack Horner a
Little Bo Peep? But why should we stop at ar
and nursery rhymes? Why not resolve etymolo
completely into its psychological meaning? Sla
terms and expletives would be easy, the mark of
phallus would readily be unearthed. Many ordina
words could be resolved into some beastliness. Th
"slowly"; note the sinister sibilant, followed by
peculiar expression of the parturient cow and
terminal diminutive. Another example, the name
the first object I see on looking up, "picture
pic-pick, obviously a triune phallus and ure, Goeth
Sir Urien, Silenus, urine. These will suffice,
many words could be made unpleasant and
exceptions classed as of uncertain derivation; th
with the help of the excretory and genital process
we should have a new psychologic etymology.

We are going too far. Already we incur
ridicule of the laity. In one best seller it is relat
that the social "worker" gained more and m
interest from the girls he "analysed," for th
guessed what he wanted. Evoe in his parable of
dogs (*Punch*, Dec. 10th, 1930) coins the beautiful w
"psychothomphoolery." There is no doubt th
sex, an important part of the ego, is of some impo
ance in the ætiology of mental sickness, but it is

the only factor; it is highly probable, too, that sexual symptoms are secondary to somatic abnormalities.

What happens to the patients who submit to the practitioners of this sexual cult? I see a number of them afterwards. One of them told me that her examiner was so insistent on her having committed, in thought or deed, some indecency, that she fabricated a story which immediately satisfied him. Even if truth, or perversion of truth stimulated by the suggestion of the examiner, is achieved, what is the benefit? The patient is briefly gratified by a new "explanation," couched in the fashionable language which converts what should be the stigma of worthlessness (sickness) into an interesting, even laudable, "complex." But apart from this gratification and that derived from conversation with the more prurient of his acquaintances, he is left where he was.

One example may help to impress my meaning. A youngish medical man consulted me for vague bodily complaints. He was nearly useless, as he had no interest in anything but himself, and he was miserable because he had been unable to cope with work; he had thrown up one post after another and now was unable to face any occupation. He was in fair health and strength, but questioning elicited symptoms of dyspepsia and constipation. He "reacted" to a careful question as to sexual condition with marked reticence, and I did not take a muck rake and stir this slough. It was obvious that he had many complexes, and had been told so. A careful examination showed duodenal infection with hypochlorhydria and a hypertrophic and atonic colon. I left his complexes alone, gave him kaolin, acids, and raw cabbage salads daily. Now, two years later, he writes to say that he is really making good as he has an interesting and growing practice.

Sex is a part, not the whole. What should be the first law of psychology is ignored—Mens sana in corpore sano; the converse should be the second law. Let us first examine the body and its habits, correct, when possible, the errors found. Then with tact and endurance lead the patient onwards until his body is healthy again, and leave the healthy body to heal its sick mind.

I am, Sir, yours faithfully,

Bristol, Jan. 19th, 1931. A. T. TODD.

INTRAVENOUS ANTISEPTICS FOR UTERINE INFECTION.

To the Editor of THE LANCET.

SIR,—With reference to your annotation on this subject in THE LANCET of Jan. 17th (p. 143), a report on the clinical effect in puerperal sepsis of intravenous injections of an acridine dye by Dr. Phillip Oginz of King's County Hospital, New York, published in the *American Journal of Surgery*, November, 1929, is of interest. Oginz used the acridine derivative rivanol (2-ethoxy-6-9-diamino-acridine lactate) and his records are taken from a series of 150 cases. To control results the drug was used only on alternate cases diagnosed as pure sepsis during what he describes as an unfortunate "epidemic" of puerperal infections which occurred in 1924.

The results in one of the case groups may be taken as typical, where the average number of days of fever in the cases treated with intravenous rivanol was 4·8 and where that of the controls was 13·3; the average stay in hospital of the cases treated with rivanol was 14·4, that of the controls being 23·3. The method of administration of this antiseptic appears very simple, 0·1 g. was dissolved in 100 c.cm. of boiling water to make a 1 : 1000 solution, 0·3 g. of sugar being added to each 100 c.cm. For administration 60 to 80 c.cm. of the 1 : 1000 solution was warmed to body temperature and injected very slowly, at least 25 minutes being taken to administer the fluid. Care must be taken, he states, to keep the needle in the vein, as the fluid is irritating to the subcutaneous tissues.

Oginz describes the clinical effect of an injection as follows: "The temperature drops as by crisis within 24 hours. If it subsequently rises, the peak is lower than before. A second injection sends the temperature down to normal, where it usually remains. It is only rarely that more than two doses are required. With the drop in temperature the general condition of the patient improves. Where a positive blood culture has been obtained the effect of rivanol is to render the blood sterile, so that usually after the second, or certainly after the third, injection a positive blood culture can no longer be demonstrated." Whether this is the direct bactericidal effect of the rivanol, or the result of a mobilisation of the body's defensive tissues and fluids, would seem to merit more detailed and extensive experimentation.

I am, Sir, yours faithfully,

GEORGE H. MORRISON, M.B., Ch.B.

THE STRUCTURE OF NEUROSIS.

To the Editor of THE LANCET.

SIR,—In the discussion following Dr. Alfred Adler's lecture on p. 137 of THE LANCET for Jan. 17th, at the end of some remarks I am reported as asking: What happened when an individual could not react normally because of some purely physical disability—for instance, in the organ of the mind itself, as a result of epidemic encephalitis—which I thought "was as well explained by the theory of inferiority as by any other." What I really meant was that behaviour-alterations which occasionally followed epidemic encephalitis might sometimes represent an "inferiority complex," resulting (indirectly) from the physical damage to the organ of the mind.—I am, Sir, yours faithfully,

Harley-street, W., Jan. 17th, 1931. F. PARKES WEBER.

CLINICAL CONDITIONS ASSOCIATED WITH ACHLORHYDRIA.

To the Editor of THE LANCET.

SIR,—In his Schorstein lecture, to which Dr. Hurst refers us, he makes the following statement under the heading of achlorhydria[1]:—

> "It has always been assumed that the achlorhydria is a result of the carcinoma, although none of the numerous theories which have been proposed to explain its occurrence appeared to be satisfactory. A study of the data obtained in our cases, and of those published by other investigators, has convinced me that this assumption is unjustified, and that the achlorhydria is a result of chronic gastritis, which precedes the onset of the carcinoma, and is in fact the most common predisposing condition."

This suggested to us that he regarded achlorhydria as the most important factor in carcinoma of the stomach, and we are sorry if we have misinterpreted him. I am, Sir, yours faithfully,

Manchester, Jan. 19th, 1931. T. H. OLIVER.

ACUTE TOXIC HEPATITIS AFTER ACRIFLAVINE.

To the Editor of THE LANCET.

SIR,—An annotation appearing in THE LANCET of Jan. 17th recommended intravenous acriflavine as worthy of trial in early cases of uterine infection. The drug, however, appears to be not devoid of dangers. In the following case the antiseptic was given orally. A man, aged 34, with gonorrhœa but otherwise in good health, received acriflavine by mouth gr. ½ four-hourly by day for two months (probably about 10 grammes in all). At the end of this time he developed jaundice, vomiting, drowsiness, and coma and died at the end of 14 days from the onset of these symptoms. His doctor informs me that at autopsy the liver was small, soft, and yellow. Histologically the liver shows the typical changes of acute toxic hepatitis. There was nothing to suggest a cause for the hepatitis, a condition unknown in gonorrhœa, except that the patient had been given acriflavine. How extensively the drug is given by mouth I do not know, but in the district from which the case came it has been employed as part of the routine treatment of gonorrhœa, and tablets for oral administration, gr. ½ t.d.s., are on the market.

There are a few references in the literature[1] [2] [3] [4] to various mild and immediate symptoms following the exhibition of the drug, but there is only one article which records delayed symptoms and grave hepatic involvement in man. Major D. H. Murray, in Egypt, investigated 118 cases (112 of gonorrhœa and 6 dermatological) which had been treated with intravenous injections of acriflavine.[5] The total dosage in each case ranged between 0·1 and 2·6 grammes. No immediate ill-effects followed the giving of the drug, but after a lapse of eight or more weeks from the final injection as many as 11 per cent. developed what was thought to be catarrhal jaundice. All save one recovered. The fatal case was of great interest. A total of 1·0 g. acriflavine had been administered and eight weeks after the last dose the patient developed jaundice and died within 21 days of the onset. The diagnosis of acute yellow atrophy was confirmed at post-mortem, both macroscopically and microscopically. It was then found that whereas the occurrence of "catarrhal jaundice" among those who had been treated with acriflavine was 11 per cent., the incidence of this disease among the remainder of the troops in the Egyptian Command was only 0·32 per cent. Major Murray concluded that there was a definite relationship between the former cases and the giving of acriflavine. It is important to note that he showed that the size of the dosage had no bearing on the occurrence of the jaundice, and he thought that it must have been due to an idiosyncracy on the part of the patients. In view, however, of the high percentage of 11 he felt that the use of acriflavine intravenously was both dangerous and unjustifiable in the treatment of gonorrhœa. In 1925 Meleney and Zau[6] published some experiments showing that a single intravenous injection of 0·00025 g. per kilo body-weight invariably killed a rabbit within six days and that death was associated with degenerative lesions of the liver and kidney.

There seems good evidence therefore that acriflavine given intravenously may cause grave liver damage. There is little reason to suppose that any less serious results may follow giving the drug by mouth than by the intravenous route, and the present case seems to confirm the view of Major Murray that acute toxic hepatitis may be one of the sequelæ. It is not clear in this instance whether or not the patient had an idiosyncracy to the drug. But in any event it is difficult to avoid the conclusion that the oral administration of acriflavine may sometimes be followed by serious consequences.

I am, Sir, yours faithfully,
EDWARD R. CULLINAN.

LEAKAGE FROM OXYGEN CYLINDERS.

To the Editor of THE LANCET.

SIR,—I would like to call attention to the need of some official regulation to prevent oxygen cylinders from being sold to the public without some guarantee that there has been no serious leakage. Recently the father of a young patient of mine bought two cylinders of oxygen from a local chemist and found them to be almost empty. The need was urgent and the delay might have had serious consequences. Some manufacturers stamp cylinders with their weight full and empty. If this marking were made compulsory the chemist might be required to note the weight when actually sold and at least to adjust the price according to the contents of the cylinders if he cannot supply a full one. For a man earning between £2 and £4 a week the price of a cylinder (12*s*. 6*d*.) is no inconsiderable item, and for this sum he can only buy an invisible pig in an opaque poke (returnable). No stopcock in my experience remains airtight for a period of years, and in small provincial towns the demand for oxygen may be very irregular.

I am, Sir, yours faithfully,
Gillingham, Kent, Jan. 19th, 1931. B. W. ROFFEY.

SERUM TREATMENT OF LOBAR PNEUMONIA.

To the Editor of THE LANCET.

SIR,—In your issue of Dec. 27th, 1930, there are two papers which report favourable results in the treatment of lobar pneumonia by means of Felton's serum prepared by the Lederle Laboratories. This was again referred to in an annotation on Jan. 3rd. Boots Pure Drug Co., Ltd., have placed their distributing facilities at the disposal of the Lederle Laboratories, and are now holding supplies of this special serum which are immediately available for the use of medical men in this country. The serum is supplied ready for use in a syringe, each syringe containing 10,000 units Types I. and II.

I am, Sir, yours faithfully,
P. C. BRETT,
Director, Boots Pure Drug Co. Ltd.
Nottingham, Jan. 20th, 1931.

UNIVERSITY OF CAMBRIDGE.—Dr. A. E. Barclay has been appointed University lecturer in medical radiology and electrology.

ENLARGEMENT OF NORTH ORMESBY HOSPITAL.—This Middlesbrough hospital, which is connected with the Anglican community of the Holy Rood, is to be enlarged at a cost of £16,000. The extensions will include three children's wards and two observation wards, sterilising and anæsthetic rooms, surgeons' rooms, two recovery wards, and a theatre for ear, nose, throat, eye, and minor surgery.

OBITUARY

ETHEL BENTHAM, M.D. Brux., M.P.

Dr. Ethel Bentham, who died at her home in Islington early on Monday morning, in her seventy-first year, was the first medical woman to win a seat in the House of Commons.

Born in London, Ethel Bentham was the daughter of the late William Bentham, a Quaker and a Justice of the Peace for the county of Dublin. She was educated at the Alexandra School and College in Dublin, where she organised a Sunday club for shop girls. Deciding to take up medicine as a means of entry to the homes of the poor, she studied at the London School of Medicine for Women, but was obliged to obtain statutory qualifications elsewhere. In 1893 she took the L.M. of the Rotunda Hospital, Dublin, in the following year the triple Scottish qualification, and in 1895 the M.D. of Brussels. After serving as assistant medical officer to the Blackfriars Provident Dispensary for Women and Children, and clinical assistant at the New Hospital for Women, she entered on general practice at Newcastle-upon-Tyne, where she remained for some 15 years, standing unsuccessfully for the city council, which then consisted exclusively of male members.

DR. BENTHAM.

[*Photograph by Elliott & Fry.*

Twenty-five years ago Dr. Bentham removed to London to become a general practitioner in Kensington and to play an active part in local affairs. Here, as in Dublin and Newcastle, her interest in a patient was unsatisfied unless she knew the conditions of work and wages. In any problem affecting the lives of the workers she essayed to answer the age-long question, "Am I my brother's keeper?" It was on her initiative that in 1911 a baby clinic in Kensington was opened as a memorial to Margaret MacDonald and Mary Middleton, and under her guidance this developed into an important and useful centre. The aim of the Women's Labour League in establishing it was to avoid the delays and neglects arising from the distance of hospitals, late diagnosis, and non-recognition by parents of conditions needing attention. Within two years an antenatal clinic was added, then a mothers' dental clinic, later still a hospital with 20 beds for children under five who needed prolonged treatment for such conditions as rheumatism, rickets, and malnutrition. Finally, at the request of the London County Council, the centre undertook the treatment of minor ailments for older children, and a school dental clinic was added. All this while the clinic was worked by general practitioners in strict harmony with other private practitioners in the area. Dr. Bentham herself became ever more convinced that this work was preventing and cutting short the multitudinous ailments of young children, and that in such small centres within easy reach of the homes would be found the real solution of prevention of disease, in so far as prevention lay within the scope of purely medical measures.

In public affairs Dr. Bentham took the prominent place which her enthusiasm and social gifts assured her. For 13 years she was a member of the Kensington borough council. She was one of the first women to be placed on the Commission of Peace, and was soon made chairman of the court dealing with non-attendance at school, always being present when the Bench sat as a children's court. She was a diligent member of the Metropolitan Asylums Board. She served on the national executive of the Labour Party, and finally, in 1929, was elected Member of Parliament for East Islington, after having stood unsuccessfully on three previous occasions.

Dr. E. Honor Bone writes: "All achievement in a life like that of Dr. Ethel Bentham is to be estimated not only by its own completeness but also by its power to influence and to inspire beyond its own immediate sphere. Judged in this way it may be said that one of Dr. Bentham's most important contributions to the social welfare of her time was the inception of the baby clinic. Medical inspection of school-children had long been established in this country, and its value proved, but this woman realised in the course of her practice that the start in preventive medicine should really be made in the earliest months of a child's life, and that it should therefore be possible for mothers to bring their children to some centre where they could get advice about diet and hygiene, and where the doctors would have an opportunity of detecting the first signs of infantile disorder which, if unchecked, might lead to well-marked disease. Many infant welfare centres now exist, and they are firmly established as an integral part of the country's health services, but probably few people realise that the pioneer baby clinic came into existence in Kensington as a memorial to Mary Middleton and Margaret MacDonald—two famous friends of childhood. The suggestion that this was the most fitting memorial to two such women came from Ethel Bentham. The new clinic attracted visitors from far and near, and the idea was carried into other districts, where it flourished even during the difficult years of the war.

"Ethel Bentham had no patience with palliatives. She wanted to get to the root of all social troubles. This was apparent throughout her work, and it was inevitable, therefore, that in her efforts to improve the health of the nation she should begin with the child. It is interesting to reflect that one sharp-cut impression of the Dublin slums, where she became acquainted with the deepest misery of the people, dated back to her childhood's years. Her mother had taken her on some errand of mercy to a tenement house. In a squalid room sat a group of children around a table on which lay a baby in a coffin. One feels how often that scene must have restaged itself in her mind as she worked in the poor districts of Newcastle and Kensington, colouring her views on the housing question and creating a lasting sympathy for the child bred in poverty. It pleases her friends to know that at the very last Ethel Bentham had the gratification of receiving signal recognition of her work. At No. 10, Downing-street a gathering took place in her honour, the Prime Minister expressing the most cordial appreciation of the work she had done for the Mary Middleton and Margaret MacDonald Clinic, and presenting her with an illuminated volume containing its annual reports.

"Ethel Bentham saw a vision—the small child in the poor house preserved from illness rather than cured of it. Her hard common sense and driving energy enmeshed this ideal in terms of the practical. To-day all over the country baby clinics and welfare centres hold their watching brief for the young, and testify to the pity, the wisdom, the constructive mind, and the executive ability which captured the vision splendid."

JOHN JENKINS, M.R.C.S. Eng.

Dr. Jenkins, who died at the Hammersmith Hospital in Ducane-road, Shepherd's Bush, on Jan. 3rd after a brief illness, had been in charge of the hospital from its opening in 1905. Born at Maesteg, Glamorgan, in 1869, he was educated at Cowbridge Grammar School and the University of Wales, going on to University College Hospital, London, for his clinical study, and qualifying in 1902. In December of that year, after a short experience at mental hospitals in the London area, he became assistant to Dr. C. Thackray Parsons at the Fulham Hospital in St. Dunstan's-road, Hammersmith, where he remained until his appointment as a principal. During the war his hospital was taken over by the military authority for orthopædic cases, and he received the rank of Major, R.A.M.C., as officer in charge. Later he became a member of the medical service board of the Ministry of Pensions, and for a long time presided over the military invaliding board. Of his work as a hospital administrator Dr. Parsons writes: "The improvement of his hospital, the maintenance of it in the front rank of the London poor-law infirmaries, absorbed him. He wore himself out in his devotion to it. He knew how to get the best out of his staff, to stimulate them in their work, and to maintain a strict discipline whilst retaining their affection. His was a full life. Work time and leisure time he filled with interest. He read widely and with discrimination; he was a good shot. Keenly interested in all mechanical things, motoring was one of his great joys. With his genius for friendship he had a wide circle of friends, and bound them to him by his sympathy and practical advice and help in difficulties. Married in 1905, no man was more fortunate in his wife. They were never apart from the day of their marriage, and were one in thought, interests, and aims. We who knew him knew how much he owed to her in times of stress and in times of peace."

CHUNG YIK WANG, M.D., F.R.C.P. Edin.

From Hong-Kong comes the news of the death of Dr. C. Y. Wang, professor of pathology in the University at the early age of 42. Prof. Wang was the youngest of five sons of the Rev. Yuk Cho Wang, of Hong-Kong; he was educated at Queen's College there, and at Edinburgh and Manchester Universities, taking the highest distinctions in medicine at the former and in science and public health at the latter. He also graduated with honours at the Hong-Kong College of Medicine, sharing the gold medals with his brother Chung Ching. After obtaining these qualifications he returned to Edinburgh and worked in the department of bacteriology and pathology at the Royal College of Physicians under Prof. James Ritchie, being also assistant superintendent of the bacteriological department at the Royal Infirmary. The outcome of this experience was a series of papers on complement fixation in tubercle and syphilis, and on other serum reactions, a number of which appeared in our own columns. One of the most exhaustive of these dealt with a precipitation test carried out in parallel with the Wassermann reaction with remarkably concordant results; the work begun at Edinburgh was brought to a conclusion in his own department at Hong-Kong. As was natural at Edinburgh he became interested in tuberculosis of bovine origin and his writings cover such subjects as the frequency of tuberculous infection, the isolation of tubercle bacilli from sputum, and an experimental study of latent tuberculosis. He also elaborated a new culture medium for the tubercle bacillus. It was in 1920 that he was appointed to the chair in Hong-Kong, and each year since has seen some original contribution from his pen, including a small handbook of pathology. Whilst still in Edinburgh Prof. Wang married Miss Florence Maud Folkard who, with two sons, survives him.

MEDICAL NEWS

University of Oxford.

At recent examinations the following candidates satisfied the examiners in the undermentioned subjects:—

Medicine, Surgery, and Obstetrics.—G. H. Bateman, Fairfax Bell, R. T. V. Clarke, F. R. Crookes, H. R. J. Donald, H. C. Harley, R. S. Harrison, M. A. Hatt, J. M. Lees, R. D. Newton, N. C. Parfit, W. G. Rees, E. H. Rink, B. T. Squires, and F. M. Trefusis.

Forensic Medicine and Hygiene.—E. J. Baldwin, D. S. Bateman, G. H. Bateman, R. R. Bomford, N. P. Bruce, J. M. L. Burtenshaw, F. R. Crookes, T. M. Davie, H. W. Davies, Newton Heath, J. H. Hunt, K. N. Irvine, O. M. Capper Johnson, H. de B. Kempthorne, R. M. Marshall, Q. St. L. Myles, M. W. C. Oldfield, W. G. Rees, E. H. Rink, and B. T. Squires.

Pathology.—E. J. Baldwin, S. W. T. Bentall, R. R. Bomford, Edward Braithwaite, F. W. Brown, N. P. Bruce, H. W. Davies, R. C. Garman, H. F. Moseley, J. A. Nunn, T. R. Plummer, T. W. H. Porter, J. L. Ryce, G. E. Scott, J. A. E. Scott, H. C. Wadge, E. J. Williams, and C. H. Yeoh.

An examination for a Radcliffe Travelling Fellowship of the annual value of £300, and tenable for two years, will begin at the University Museum on Feb. 24th.

Candidates must have passed all the examinations required by the University for the degrees of B.A. and B.M. They must not have exceeded four years from the time of passing the last examination required for the degree of B.M. The Fellowship will be vacated by a Fellow who spends more than nine months in the whole within the United Kingdom. Papers will be set in physiology, pathology, and preventive medicine, and a subject will be proposed for an essay. There will also be a practical examination in pathology. Candidates may offer in addition a special branch of either medicine or surgery. Names, addresses, and qualifications must be sent to the Regius Professor of Medicine, University Museum, by Feb. 11th.

Society for Relief of Widows and Orphans of Medical Men.

At the quarterly court of directors held on Jan. 7th Mr. V. Warren Low presiding, the sum of £1417 10*s.* from the ordinary funds, and one of £467 10*s.* from the Brickwell fund, were voted for the half-yearly grants. Each widow over 65 receives £37 10*s.*, under 65 £25, and each orphan £25. In addition, a sum of £86 5*s.* was voted to enable orphans, who had reached the age of 16, to continue their education. In December, £630 was distributed as a Christmas present, each widow and orphan receiving £10. At the present time 53 widows and eight orphans are in receipt of grants. The Society grants relief to the widow of a member who is left with a yearly income of £125 or under. A widow who died since the last court came on the funds in 1917, and had received in grants £925, her late husband having paid a life subscription of £31 10*s.* Membership is open to medical men who at the time of their election are residing within a 20-mile radius of Charing Cross. The invested funds amount to over £140,000. Further particulars from the Secretary at the offices of the Society, 11, Chandos-street, London, W.1.

University of London.

The University Court has accepted a bequest of £4000, free of legacy duty, from Miss Mary Ethel Sim Scharlieb, who died in 1926. The purpose of the bequest is the founding of a scholarship in memory of Miss Scharlieb's mother, the late Dame Mary Scharlieb, M.S., to whose life interest the legacy was subject. The scholarship is to be called the Mary Scharlieb Research Scholarship, and the conditions of award will be determined by the university.

Hunterian Society.

A banquet to commemorate the 203rd anniversary of the birth of John Hunter will be held at the May Fair Hotel, Berkeley-street, W., on Thursday, Feb. 19th. The guests will include the Lord Mayor and Lady Mayoress of London.

Association of Public Vaccinators.

The annual general meeting of the Association of Public Vaccinators of England and Wales will be held at 1, Upper Montague-street, London, W.C., on Friday, Jan. 30th, at 3.30 P.M. All public vaccinators are invited.

Food Education Society.

Three lectures on Food and Food Habits and their Connexion with Rheumatism, Cancer, and Other Chronic Diseases, will be given by Dr. Richard Ackerley, at 29, Gordon-square, London, W.C. (entrance in Gordon-street) on Wednesdays, Feb. 11th, 18th, and 25th, at 5.30 P.M.

Post-graduate Course in Belfast.

A series of lectures is in progress at the Royal Victoria Hospital, Belfast, and will continue at 4 P.M. on Wednesday afternoons until June. A second series will begin in the autumn. Medical men who wish to take the course should apply to the honorary secretary of the medical staff of the hospital, who will supply the provisional programme.

Hampstead General and North-West London Hospital: Post-graduate School.

A post-graduate school has been established at this hospital, the membership being composed of practitioners in the north-west of London. The meetings will be held at the hospital every Wednesday afternoon at 4, when debates bearing essentially on general practice will be opened by members of the medical staff of the hospital. The published programme for the session shows that a wide range of subjects has been set down for discussion. The inaugural meeting will take place on Wednesday, Jan. 28th, at 4 P.M. when an address on Maternal Mortality and Morbidity will be given by Mr. Comyns Berkeley. Mr. Clifford Morson has been appointed dean of the school.

National Council for Mental Hygiene.

This Council has arranged a series of lecture-discussions at 11, Chandos-street, London, W., at 5.15 P.M., on Thursdays. The speakers will be: Mrs. Neville-Rolfe on Modern Marriage and Its Problems (Feb. 12th); Prof. J. E. Marcault on the Psychology of Education (19th); Dr. J. R. Rees on the Psychology of Dreams (26th); Dr. W. A. Potts on the Psychology of Punishment (March 5th); Dr. J. Burnett-Rae on the Psychology of Sanity (12th); and Dr. H. Crichton-Miller on the Psychology of Suicide (19th). Tickets are obtainable from the Secretary of the Council, 78, Chandos House, Palmer-street, S.W.1, or at the doors.

Friends of Economy.

A group of public men, drawn from all parties, and using this title, are inaugurating a campaign by a public meeting to be held in the Great Hall, Cannon-street, London, E.C., on Tuesday next, Jan. 27th, at 3 P.M. Mr. E. C. Grenfell, M.P., will take the chair, and the meeting will be addressed by Viscount Grey of Fallodon, Sir Robert Horne, and Sir Ernest Benn. The intention of the campaign is to point out the urgent national need for public economy.

Fellowship of Medicine and Post-Graduate Medical Association.

Particulars of lectures and demonstrations in the coming week will be found in our Medical Diary. From Jan. 27th to Feb. 7th there will be an intensive course in medicine, surgery, and the special departments, at the Prince of Wales's Hospital, daily from 10.30 A.M. to 5.30 P.M. Courses in February will be as follows: gynæcology at the Chelsea Hospital (2nd to 13th); tropical medicine at the Hospital for Tropical Diseases (9th to 28th); and children's diseases at the Queen's Hospital (16th to 28th). Three-months' courses in venereal disease can be arranged (for women only) at the London School of Medicine for Women. The list of courses for 1931, and copies of all syllabuses, may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W.1.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Jan. 26th.—8 P.M., ODONTOLOGY. Paper: Dr. A. A. Osman: The Importance of Sugar in the Diet of the School Child.

TUESDAY.—5 P.M., MEDICINE. Paper: Dr. J. Crighton Bramwell: The Prognosis and Treatment of Heart Disease Complicating Pregnancy.

WEDNESDAY.—5 P.M., COMPARATIVE MEDICINE. Discussion: Pathology and Treatment of Hæmopathies, including Leukæmia of Man and Animals. Opener: Dr. H. P. Bayon. Followed by Dr. J. T. Edwards, Dr. J. F. Halls Dally, Sir Thomas Horder, and Dr. J. E. A. Lynham. Other speakers will take part.

THURSDAY.—5.30 P.M., NEUROLOGY: Hughlings Jackson Lecture. Sir Charles Sherrington: Quantitative Management of Contraction for "Lowest-level" Coördination.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Jan. 26th.—8.30 P.M., Dr. E. P. Cumberbatch: Medical and Surgical Uses of Diathermy (Discussion).

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

MONDAY, Jan. 26th.—8 P.M., Prof. L. C. Martin, D.Sc.: Some Modern Developments in Microscopy (1).

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, Jan. 30th.—8.30 P.M., Colonel E. T. Burke: The Sex Factor in Determining the Course of Syphilis. A Discussion will follow.

ASSOCIATION OF PUBLIC VACCINATORS.

FRIDAY, Jan. 30th.—3.30 P.M. (at 1, Upper Montague-street, W.C.), Annual General Meeting.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.

MONDAY, Jan. 26th.—5 P.M., Mr. D. H. Patey: Pathological Basis for the Treatment of Varicose Veins and Its Bearing on Problems of Thrombosis.

WEDNESDAY.—5 P.M., Mr. J. Paterson Ross: Treatment of Cerebral Tumours with Radium, with an Account of Experiments made to Study the Effects of Radium upon Cerebral Tissue.

FRIDAY.—5 P.M., Dr. Donald Hunter: Changes in the Bones in Hyperparathyroidism and Hyperthyroidism.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 27th, to SATURDAY, Jan. 31st.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Mon., 4 P.M., free lecture by Dr. J. W. McNee, on Grave Anæmias. (Early Diagnosis series.)—ST. PETER'S HOSPITAL, Henrietta-street, W.C. Free demonstration in Out-patient Department with Cystoscopies by Mr. Swift Joly on Mon. at 2 P.M.—PRINCESS LOUISE CHILDREN'S HOSPITAL, St. Quintin-avenue, Ladbroke-grove, W. Tues., at 4 P.M., free demonstration by Dr. Jean Smith on Nutritional Disorders. (Cases.)—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N. Intensive Course, two weeks' duration, in medicine and surgery.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Jan. 26th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Children's Diseases Clinics. Operations.

Special lectures will be delivered on Mon., Tues., Thurs., and Fri., at 4.30 P.M., by Mr. E. Gillespie, Dr. J. Browning Alexander, Dr. F. Howitt, and Dr. L. R. Yealland, respectively

CHARING CROSS HOSPITAL MEDICAL SCHOOL, Agar-street, W.C.

SUNDAY, Jan. 25th.—10.30 A.M., Dr. K. Shirley Smith: Old and New Remedies in Cardiovascular Disease. 11.45 P.M., Mr. Peter Daniel: Diagnosis of Diseases of the Rectum.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (Public Health Division), Keppel-street, Gower-street, W.C.

MONDAY, Jan. 26th.—5 P.M., Mr. J. C. Dawes: Public Cleansing. Composition and Storage of House and Trade Refuse.

WEDNESDAY.—5 P.M., Mr. J. C. Dawes: Subject continued.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

WEDNESDAY, Jan. 28th.—5 P.M. (at St. John's Hospital, 49, Leicester-square, W.C.), Dr. Haldin-Davis: The Importance of the Skin.

KING'S COLLEGE, Strand, W.C.

MONDAY, Jan. 26th.—5.30 P.M., Prof. J. Barcroft: Constancy of the Internal Environment (1).

UNIVERSITY COLLEGE MEDICAL SCHOOL, University-street, W.C.

TUESDAY, Jan. 27th.—5.15 P.M., Dr. J. A. Murray: Induction of Cancer by Tar and other Agents.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Jan. 29th.—9 P.M., Mr. John Everidge: Stone in the Urinary Tract.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.

WEDNESDAY, Jan. 28th.—4 P.M., Mr. Comyns Berkeley: Maternal Mortality and Morbidity.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Jan. 27th.—5 P.M., Dr. A. M. H. Gray: The Sarcoids.

THURSDAY.—5 P.M., Dr. W. N. Goldsmith: Lichen Planus.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, Jan. 28th.—4 P.M., Dr. Edwin Smith: The Practitioner in his Relationship to the Coroner's Court.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.

THURSDAY, Jan. 29th.—5 P.M., Mr. H. Burt-White: Investigation and Treatment of Puerperal Pyrexia.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Jan. 30th.—4 P.M., Mr. Nicol Rankin: Differential Diagnosis in a Case Complaining of Nasal Discharge.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 27th.—3.15 P.M., Mr. N. A. Jory: Lecture.

Appointments

BIRCH, C., L.R.C.P. Lond., M.R.C.S., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Chipping Campden, Gloucester.

DARLING, ISABELLA C., M.B., Ch.B. Glasg., D.P.H., Asst. School Medical Officer, Lanarkshire.

POOL, A., M.B., Ch.B. Liverp., Visiting Psychologist to the Walton Hospital, Liverpool.

THOMAS, J. G. S., L.R.C.P. Lond., M.R.C.S. Eng., Medical Officer to the Post Office, Box, Wiltshire.

Cardiff Royal Infirmary: HAYCRAFT, J. BERRY, M.B. Edin., F.R.C.S. Eng., and JONES, DAVID J., M.B. Lond., F.R.C.S. Eng., Honorary Assistant Surgeons.

London County Council: CRAIG, J. A., M.B., B.Ch. R.U.I., Asst. M.O., Bethnal Green Hospital. ELLIOT-SMITH, A., F.R.C.S. Eng., L.R.C.P. Lond., Asst. M.O., St. Giles' Hospital, Camberwell. LEONARD, F. R., M.B., Ch.B. Otago, Asst. M.O., South-Western Hospital. MCMAHON, E. G., M.B., Ch.B. Syd., Asst. M.O., Queen Mary's Hospital, Sidcup. MCQUEEN, J. G. S., M.B., Ch.B. Edin., Asst. M.O., Colindale Hospital. PARISH, T. N., M.B., B.Chir. Camb., Asst. M.O., St. Giles' Hospital, Camberwell. PRICE, S. R. C., L.R.C.P. Lond., M.R.C.S., Asst. M.O., St. Luke's Hospital, Lowestoft. SWINTON, C. F., M.B., Ch.B. St. And., Deputy Med. Super., Hackney Hospital.

Vacancies

For further information refer to the advertisement columns.

Altrincham General Hospital.—Sen. and Jun. H.S.'s. At rate of £150 and £120 respectively.

Bath, Royal United Hospital.—Surgeon to Ear, Nose, and Throat Department.

Birkenhead, County Borough.—Assistant for Municipal Laboratory. £240.

Birmingham, City Babies Hospital, Canwell Hall.—Res. M.O. At rate of £100–£150.

Bolton, Townleys Hospital, Farnworth.—Asst. M.O. £225.

Bradford Children's Hospital.—Hon. Asst. Surg.

Bradford Royal Infirmary.—Two H.S.'s. Each at rate of £150.

Brighton, Steyning Institution.—Res. M.O. and Asst. Administrative County M.O. £600.

Bristol, City and County.—Asst. M.O. for Maternity and Child Welfare. £500.

Bristol Eye Hospital.—Res. H.S. £150.

Bristol Royal Infirmary.—H.P.'s and H.S.'s to Special Depts. All at rate of £60.

Cancer Hospital, Fulham-road, S.W.—Physician.

Canterbury, Kent and Canterbury Hospital.—H.S. At rate of £125.

Cardiff Royal Infirmary.—H.P.'s and H.S.'s to Special Depts. All at rate of £50.

Charing Cross Hospital, W.C.—Asst. Obstetric Physician.

Chester Royal Infirmary.—H.S. to Ear, Nose, and Throat Dept. £150.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Eastbourne, Ear, Nose and Throat Hospital.—Hon. Surgeon.

Evelina Hospital for Children, Southwark, S.E.—H.P., Cas. and Out-patient Officer. Also H.S. All at rate of £120.

French Hospital and Dispensary, 172, Shaftesbury-avenue, W.C.—Jun. Res. M.O. £100.

Fulham School Medical Treatment Centre, Bagleys-lane, Fulham, S.W.—Surg. to Eye Dept., £200; Surg. to Ear, Nose, and Throat Dept., £120; Anæsthetist to ditto, £75; Radiologist, Ringworm Dept., £40; Anæsthetist to Dental Dept., £75; Surg. Minor Ailments Dept., £66.

Glasgow University.—Harry Stewart Hutchison Prize. £50.

Great Yarmouth General Hospital.—Sen. H.S. £150.

Harrogate Infirmary.—Jun. H.S. At rate of £125.

Hertford County Hospital.—H.P. £150.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—H.P. At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Surg. Reg. £300. Also Refraction Asst. for Ophthalmic Dept. 1 gn. each attendance.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—Asst. Radiologist.

Ilford, King George Hospital.—Hon. Gynæcological Surgeon.

Inverness, Royal Northern Infirmary.—H.S. At rate of £105.

Leicester, City Isolation Hospital and Sanatorium, Groby-road.—Jun. Asst. M.O. £300.

Leicester City Mental Hospital, Humberstone.—Second Asst. M.O. £350.

Leigh Infirmary, Lancashire.—Res. H.S. At rate of £200.

Liverpool County Borough Local Educational Authority.—Jun. Asst. School M.O.'s. Each £500.

London Female Lock Hospital, 283, Harrow-road, W.—Surg. Reg. £100.

Manchester, Ancoats Hospital.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.

Manchester, Royal Children's Hospital, Pendlebury.—Hon. Ophth. Surg.

Margate Royal Sea Bathing Hospital, &c.—H.S. At rate of £200.

Maudsley Hospital, Denmark Hill, S.E.—Asst. M.O. (full time). £435. Also Asst. M.O. (part time). £300.

Middlesbrough Education Committee.—Sen. Asst. School M.O. £500.

Minehead and West Somerset Hospital, Minehead.—Res. H.S. At rate of £150.

Newcastle-on-Tyne, Royal Victoria Infirmary.—Six Jun. Surg. Registrars. Each £150. Also Sen. and Two Jun. M.O.'s. At rate of £200 and £100 respectively.

Nottingham and Midland Eye Infirmary.—Res. H.S. £200.

Oldham County Borough.—Asst. M.O.H. and Clin. Tuber. O. £750.

Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.

Oxford City.—Temporary Asst. M.O.H. £500.

Pontefract General Infirmary.—R.M.O. £200–£300.

Poole, Dorset, Cornelia and East Dorset Hospital.—H.S. At rate of £150.

Portsmouth, St. Mary's Hospital, St. Mary's Institution, &c.—Third Asst. Res. M.O. £250.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, Kensington, W.—Hon. Asst. Dental Surgeon.

Queen Mary's Hospital for the East End, Stratford, E.—Hon. Dental Surgeon.

Rochdale Infirmary and Dispensary.—Jun. H.S. £200.

Rochester, St. Bartholomew's Hospital.—Third Res. M.O. At rate of £175.

Royal Northern Hospital, Holloway, N.—Asst. Surg. O. £75. Also Hon. Surg.

St. Bartholomew's Hospital, E.C.—Surgeon.

St. Mark's Hospital for Cancer, City-road, E.C.—Res. Surg. O. £150.

Salisbury General Infirmary.—H.S. £150.

Sheffield, Royal Hospital.—Ophth. H.S. £120. Also Res. Anæsthetist. £80–£100.

Sheffield Royal Infirmary.—H.S. At rate of £80.

Simla, Indian Research Fund Association.—Entomologist. Rs.1500 per mensem.

South London Hospital for Women, South Side, S.W.—Anæsthetist. 10*s.* 6*d.* each attendance.

South Shields, Harton Hospital.—Two H.S.'s. Each £150.

Swindon and North Wilts Victoria Hospital, Swindon.—M.O. £125.

Uxbridge, Hillingdon Hospital.—Dispenser. £250.

West Ham County Borough.—Jun. Asst. M.O. £500.

Wigan, Royal Infirmary.—Third H.S. At rate of £150.

Wolverhampton, Royal Hospital.—Two H.S.'s. Each at rate of £100.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Great Haseley (Oxon.), Langport (Somerset)), and at Towyn (Merioneth).

Births, Marriages, and Deaths

BIRTHS.

ANDERSON.—On Jan. 12th, at Ribblesdale House, Hornsey, N., the wife of Roy Shirras Anderson, M.R.C.S., L.R.C.P., of a daughter, prematurely.

MARRIAGES.

HARDY—MCNALTY.—On Jan. 14th, at St. Peter's, Eaton-square, Ernest A. Hardy, M.R.C.S., L.R.C.P., L.D.S., to Frances Joy St. George McNalty, daughter of Brigadier-General A. G. P. McNalty.

DEATHS.

BENTHAM.—On Jan. 19th, at Beaufort-street, S.W., Dr. Ethel Bentham, M.P., aged 70 years.

CAMERON.—On Jan. 11th, at Beverley, James Cameron, M.D. Lond. and Edin., M.R.C.P., aged 65 years.

DOWSE.—On Jan. 16th, at Suva, Littleham Cross, Exmouth, Thomas Stretch Dowse, M.D., aged 94 years.

LLOYD.—On Jan. 16th, at his residence, Ashlea, Abergavenny, suddenly, Thomas Edward Lloyd, F.R.C.S., M.D., M.R.C.S., L.R.C.P.

MORGAN.—On Jan. 15th, at Letchmore Lodge, Elstree, Harry de Riemer Morgan, M.A., M.R.C.S., L.R.C.P., D.P.H.

PALMER.—On Jan. 15th, at Holford, Longfellow-road, Worthing, Frederick John Morton Palmer, M.B. Lond., F.S.A., aged 7[illegible].

TURNER.—On Jan. 17th, at Guy's Hospital, after an operation, Frederick Meadows Turner, M.D., Medical Superintendent, South-Eastern Hospital; aged 64.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

ALCOHOL AND THE MOTORIST.

AT a meeting of the Society for the Study of Inebriety on Jan. 13th the chair was taken by Mr. W. McAdam Eccles, and Dr. Courtenay Weeks read a paper on Alcoholic Indulgence in Relation to Motor Transport. Whatever might be said of moderate drinking at other times, he said, alcoholic indulgence immediately before or during motor driving was a positive menace to society. The pedestrian also had a definite personal responsibility, for indulgence on his part might render him a danger not only to himself but also to others. During the year 1929 there had been 111,432 accidents—4968 of them fatal—caused by mechanically propelled vehicles. The loss of life and limb was serious enough, but these accidents also threw a strain on the financial and personal resources of voluntary hospitals; the estimated cost of accidents in the U.S.A. was 850 million dollars p.a. In addition, there were the accidents due to aviation. During 1929 there had been 1230 convictions for being drunk in charge of a car, and a large number of charges which had not resulted in conviction. All classes had been involved in these cases, which had revealed an astounding universal ignorance of the essential effect of alcohol upon the human organism. The causes of road accidents had been considered in three reliable calculations: the report of the Royal Commission on Transport; the investigation of the Roads Department, 1928–29; and returns from coroners. The first referred to 723 inquests, and ascribed 39 per cent. of the deaths to causes presumably under the control of the driver, 43 per cent. to pedestrians, and the remainder to the vehicle, road, or other non-human agency. The principal faults were excess speed (15 per cent.), inattention and lack of judgment (6 per cent.), lack of caution at cross-roads (5·8 per cent.), failing to keep to near side (3 per cent.), and cutting in (4 per cent.). Thus 80 per cent. of these accidents were due to inefficient control by driver or pedestrian. In the second investigation the driver had been held responsible in 50 per cent. of accidents, and in the third investigation 85 per cent. had been ascribed to errors of judgment on the part of motorist or pedestrian. From these figures it emerged that at least 2009 deaths in 1929 were due to negligence on the part of drivers, and 2403 to negligence of pedestrians. Intoxication, however, had only been cited in 0·7 per cent. The Air Ministry report stated that about 70 per cent. of the air accidents were due solely to faulty pilotage.

There was a large presumption that published figures of drunkenness only represented a fraction of the whole. There was need for education of public and police. Solicitors, barristers, and doctors, called for the defence, frequently said that their client could not be drunk, while admitting that he had taken considerable quantities of alcohol, such as six beers and a whisky, or seven mixed drinks in six hours. One doctor had said that he would "certify a man as drunk if he was absolutely paralytic." While such statements were made in the courts of law, it was justifiable to assume that a great number of people on the road were definitely and dangerously under the influence of alcohol.

THE PERSONAL FACTOR.

It was difficult to analyse personal errors of judgment or to express exactly what was meant by negligence. Certain types, however, constituted a definite danger without alcohol, and with it a positive menace. These were the reckless road-hog, who showed want of thought, consideration, and courtesy, as well as lack of judgment; the careless road-hog, who took out a car in an improper condition and never gained proper control either of himself or of his car; the driver with no road sense, though quite well-meaning; the emotionally unstable, who went to pieces in emergency; and those suffering from physical defects. Some of these descriptions might also be applied to pedestrians.

A New York calculation had shown that chance played a very small part in accidents. Certain drivers were especially liable to mishap. Alcohol was well known to interfere with accuracy of judgment and neuromuscular coördination. Miles's experiments, among others, had shown this ("Alcohol: Its Action on the Human Organism"). A person under even a small dose of alcohol was one whose mind lacked temporarily its normal factor of judgment and conspicuous elements of self-control. Moreover, the taking of alcohol during or before prolonged or severe exposure to cold was dangerous. A recent correspondence in the *Times* had shown how little this fact was appreciated by the public, including the Air Ministry.

An important part of the effect of alcohol in relation to driving was the lengthening of the reaction time and the deceptive influence under which the subject thought he was performing his task much better than usual, whereas he was conspicuously slower and less efficient. Car-driving demanded instantaneous response through a complex system of reflexes. The Berlin police had issued a warning that motor drivers ought to refrain completely from all alcoholic beverages, as the smallest quantities were injurious for them. A number of continental aviation organisations required abstinence during and before flight, and the majority of private and public motor companies in this country had a rule or understanding that no alcohol should be taken by drivers on duty.

DISCUSSION.

In reply to a question by Lady Horsley, Dr. Weeks said that by indulgence he meant the ingestion of any alcohol at all. The Chairman quoted from the pamphlet issued by the British Medical Association, and remarked that the offence of being drunk had been extended to cover being under the influence of drugs. Many prosecutions had been reported, and very many more must have occurred. Dr. Coram James asked whether the experiments quoted by Dr. Weeks had been made on abstainers or moderate drinkers. Dr. Weeks replied that Miles's experiments had been done on moderate drinkers. Dr. T. Rushbrooke mentioned that in a recent case the defence put forward had been that the accused had been taking cough mixture. He was glad to see that the offence of being under the influence of drugs had been included in the new Act. Dr. Weeks replied that a number of cough mixtures contained anything from 28 to 65 per cent. of absolute alcohol. Dr. H. M. Vernon remarked on the necessity for educating the public, and said that they did not understand what a long time it took to get rid of even a moderate amount of alcohol from the body. A pint of beer took three hours to remove, and even next morning a moderate drinker might have an appreciable amount of alcohol in his body. Five or six hours was not sufficient to eliminate more than a quart of beer. It was best to observe the general rule that no drink should be taken before the day's work was over. Dr. W. M. Feldman asked if Dr. Weeks knew of any experiments on the effects of tobacco on the control of the nervous system or the reaction time, or on the combined effect of alcohol and tobacco. Dr. Weeks said that he was unable to give any authority, but thought it possible that smoking might in many cases tend to increase the reaction time.

THE CHORION AND TROPHOBLAST.

THE fate of the zona pellucida of the impregnated ovum is doubtful, at least in the human subject. The doubt, of course, is due to the fact that it disappears during stages which are unknown at present. Dr. F. A. Stahl, in a monograph published a few months in looking, with another person or thing. It means a connexion. When we see, our eyes are functioning rightly only if we are socially interested, and we find among many children and grown-ups that they do not coöperate with their eyes, they do not look straight, they are not interested. We speak of a "hang-dog" or a "vacant" look, and we know the queer look of an insane person, interested only in himself. If we judge rightly, we shall find the degree of coöperation from how a person is looking. We act in a sympathetic way, and we do not like a certain look if we do not find social interest in it. We know the "dirty" look, the look of the criminal, and so on, and we judge, without knowing it, the degree of coöperation. We do not mean "looking" merely in the physiological sense of collecting pictures and leading them to the brain. What interests the psychologist is the degree of coöperation, and we understand the great importance of it because it means the whole understanding of a child if he is looking in a coöperative and interested way.

The same results will be found if we investigate in regard to listening and you can understand the little progress made by a child or by a grown-up if he does not listen interestedly, if he is not attentive, and does not connect himself in hearing sounds and words and so on, and we know how important it is for the development of one of the most important functions of the human mind—that of speaking.

Coöperation: In Social Life.

What does it mean to connect one person with another? It is the basic element of our speech function, and only such persons can speak rightly who have understood how to connect with others and to express themselves in such a way as they would like everybody to connect in speech, to express themselves in a way that others can understand, and so on. We see the development of all our sense organs can happen only if the child is socially interested; his goal is to be connected with others, and to coöperate and contribute. If he feels a part of the whole, if he feels at home upon this poor earth crust, if he wants to develop, to help to contribute, and to coöperate, then he can develop his functions rightly. What does "rightly" mean? We measure all this in regard to the welfare of the whole of mankind. We would never call anything *worth while* if it were not worth while for the whole of mankind. Normal, right, true, and so on, are things we instinctively say when it is in the direction of the welfare of mankind. For this everybody has to coöperate and to contribute. These are the primitive functions of human beings and they cannot be rightly developed if such a person is not interested in the whole and does not feel a part of the whole. In the same way, we find all the characteristics are developed in the right way only if there is a certain degree of social interest.

What do we call characteristics? These are social relations. To be *good* means to be good towards others, and to be *bad* means to be bad towards others. To be interested in Art we need a social interest; to be lazy means *not to* contribute or coöperate; just as to be industrious means the contrary, and so on. You cannot find one characteristic which does not mean a social relation which can be measured. "Courageous," for instance, is a quality that exists only in regard to the welfare of mankind. We do not find courage without social interest, and when we speak of a wrong development we mean that we do not meet with ability to coöperate. We cannot speak about morals and ethics without making it obvious that we mean coöperation and interest in others. Wherever we find that man is culturally at a certain stage, he has to grasp the ideal of coöperation. We know the meaning of life that we can develop ourselves only if we coöperate and are trained in contribution. On this point we can also answer the question we hear very often: Do we develop the individual for himself, or for mankind? Now you you *cannot* develop the individual without devel him for the welfare of mankind, and if a person develops his ability of coöperation, he develops his listening and speaking and right understanding. Our understanding, our common sense, our logic, can be strengthened and developed only in a social environment. It is based on these senses and functions of listening, looking, speaking, and so on, and our understanding is not in a proper condition unless we would understand in a way that can be controlled by the whole of mankind and as we would everybody to understand.

That is common sense. Understanding can developed only if a person is socially interested. say that failures have no common sense. They ar not stupid or feeble-minded; they conclude *rea* but not in the way of social interest. Even in regard to our æsthetic feelings we clearly judge Art by whether it is in the way of the meaning and welfare of mankind. Nobody has ever called something beautiful which was not in the line of development and improvement of mankind. And especially anything which we call beautiful in regard to human beings looks towards the future, it carries the idea of children, the tendencies of what we want mankind later on to be, and so on.

So we see our functions and feelings are developed rightly if a person is concerned about the whole of mankind and feels the need of *coöperation*. We know that the child starts with a feeling of inferiority, he feels little and down and he strives to overcome it. The only right way to overcome this feeling of inferiority, which involves everybody, is to feel *wo while*, and he cannot do so if he does not coöperate. Therefore he cannot get rid of this feeling of inferiority.

Happiness and the "Pleasure Principle."

And here is a point that I want to mention shortly. It is often said that human beings are governed by the "pleasure principle." Many psychologists and psychiatrists, however, are sure that this is not true. Human beings strive for the *happiness* of others; this is the true pleasure of the socially interested person. The "pleasure principle" is the striving of a person who is only interested in himself and not in others.

Perhaps now we feel more quiet and sure that we are on the right way. There must be an underlying idea in our life, a *meaning*, a metaphysical background of our life, which means coöperation. You will see that mankind always keeps instinctively to this viewpoint and you do not find any religious system which does not say "Coöperate; love thy neighbour." This is generally a religious explanation and if we can find a scientific explanation I believe it will help for the improvement and benefit of mankind. Perhaps we are not yet wholly sure; we want to be more sceptical, and so we ask another question. If it be really so, that the meaning of life is coöperation, then must not all our pro be problems which can be solved only if we coöperate? This is another interesting result of Individual Psychology, so that we can insist that human beings never meet anything but social problems in life which demand a right preparation for coöperation.

The Family Relation.

I spoke before about the meeting of the new-born child and the mother. Now there are other problems, small and great, in the life of the human being. Another child comes into the family and how this child behaves to the other proves his ability in coöperation. We are scared to see how many children grow up without this ability to coöperate if a new child comes into the family; how they resist and want to exclude the other child; they feel hurt and timid and do not want to coöperate, and so on. Later in life, to be sure, the child enters the kindergarten, nursery school, or public school, and always he meets a social problem. He meets other children there and the teachers, and discussions take place which are to lead towards his later profession and occupation, whether he is to be useful in the division of labour for the sake of the whole of mankind. All these problems therefore are like examinations. We can see how a child behaves in his little problems: if he wants to join other children, if he has friends and comrades, if he is interested in his work, if he can play with other children—in all these ways we find how far he is prepared in coöperation.

We are always looking for reasons why so many children, and later on grown-ups, are not rightly prepared, but this I will describe later. After the school he enters the social life, gains friendship, and a family, and he has to meet and to compare with other persons. In all these relations we find people behaving differently and if they behave rightly or, as we say, normally and intelligently, they are interested in other persons, they can coöperate. This is the social problem we meet in life. There is the problem of occupation. We have to be useful and to coöperate in the division of labour, and not believe that we are working for money. We really can earn money only if we coöperate. Otherwise we have failure in life—crime, for instance. We are paid, then, because we coöperate. The problems of society, friendship, comradeship, problems of occupation, are bound up to a certain degree. There are other problems, such as the problem of love.

The Sex Relation.

Because we are living in two sexes there must be a certain coöperation between them. In this matter mankind has felt, and feels now, that there is not the right coöperation because we are not skilled and trained and prepared. We read books which mostly are stories of unhappy marriages and love affairs, and we are impressed with the great difficulties. We are not prepared to coöperate rightly with the other person, and the problem of love demands that we should be interested in the other person more than in ourselves. This problem must be solved, and we understand that there must be such an underlying ruling idea in our lives that the meaning of life is to coöperate. We have no other problems in life.

I would be very thankful if somebody would mention a problem which does not demand social interest. We are in a trap, we cannot get out of it, and there must be a meaning of this trap. Its meaning is to coöperate. But perhaps we still want to doubt. If this is not right, it must appear in what we call the failures of life. What are failures in life? We can mention some types of failure—problem children, neurotic persons, psychotic persons, criminals, prostitutes, suicides, drunkards and morphinists, sexually perverted persons, and perhaps you know more.

The Failures.

Now in all these cases, if we are right, we shall expect to find a lack of ability to coöperate and really we do find it. We call them failures because they do not coöperate. The problem child does not contribute and therefore we are not contented with him and we want to change him so that he will coöperate. Now again we meet the same problem and the same meaning of life in the problem child and in neurotic persons. They do not coöperate; they want others to coöperate. The members of the family and the doctor should coöperate, and they will indulge, indulging and exploiting the coöperation of others, recognising the idea of coöperation—for the others.

That psychotic persons will not coöperate because they are not socially interested in others is so obvious that I do not need to speak about it. That the criminal will not coöperate is also very obvious. On the contrary, he wants to avoid coöperation and that is an easier way because he has not the characteristics of a socially interested person, which are courage and optimism, self-confidence, patience, and so on, not to be afraid of defeat, facing the difficulties of life. The criminal has not these. He is not prepared, therefore. To touch one of the most important questions of our time, I would say he is not guilty. He cannot pay what is demanded. We have to prepare him if we want to do something in regard to crime. On this point I want to say a little word in regard to determinism and indeterminism. If the child is built up for four or five years his style is fixed. This child—or later this grown-up person—can act only along the lines of that style and can change it only if he has understood the lack and mistake in his style. He has not the right meaning of life. The problem child has a meaning of life, that others must submit "I have to rule." That is the meaning of life for the problem child: "I must have my own way."

The neurotic person has a meaning of life: "the *others* have to serve and contribute." The criminal has a meaning of life: to have an easier way of earning his living, for instance; not the way of coöperation. The drunkard has a meaning of life: to escape from time to time from the problems of life where he should coöperate, always because of the fear of defeat, and because he is not sure of success. And you can see, if all the failures in life can be made more self-confident, more courageous, more interested in coöperation, they will be changed. You find the same among sexually perverted persons. They reverse the meaning of life, mostly culminating in this idea—not to be interested in procreation, the welfare of mankind, and so on.

So we see the failure has always a mistaken meaning of life: not to coöperate. Among these failures we see some interesting characteristics which may lead our understanding further. For instance, all these failures are sensitive, high-tempered, affective. They are angry, they are timid, they have all the emotions very visible, very obvious, and we can understand they are not adapted; they do not feel a part of life and of the whole. They feel always irritated and are always irritable, and we can understand it, because they are not living in this world, which means to coöperate; they have another idea of life, another meaning, and therefore they are sensitive.

They are always impatient because they are sure that their success is in danger. They do not feel strong and courageous in life. This is what we find among problem children, neurotic persons, criminals, suicides, all persons who do not find a meaning in life. They will even write in a last letter: "Life has no *meaning*, and therefore I kill myself." *They are timid.* Even criminals, you see, are cowards. We cannot be fooled by them because we have seen them escaping the social problems of life, occupation, and so on. We are sure they are not courageous, and you can see in the very structure of their crimes that they are cowards. They seek isolation, darkness, they have weapons against unarmed men, they surprise another person, and so on. They are in a majority when they attack, and so we cannot agree that they are as courageous as is sometimes believed. Theirs is always the attitude of the coward. Their characteristics agree with what we have explained; *the mistaken meaning of life.* They are also pessimistic. They do not look to the future, are not interested in the future of mankind, and are always looking for *pleasure* and not for *happiness*. So again in the failures; we find that they have failed in finding the right meaning of life which means coöperation.

Heredity: Environment: Education.

Now to another question: Whence comes this ability of coöperation? Is it an inherited instinct? Is it inborn? *That* is not possible, because, especially in regard to characteristics, we see how they must be *worked out* and *accomplished*, and how they always involve social relations which do not exist before the child is born. We have seen that we can prepare persons and correct failures and make persons more socially interested if they are convinced, as we seem to be convinced, that coöperation is the right meaning of life. Therefore it cannot be an inherited *entity*. That there must be an inherited *ability* we cannot question, because we cannot develop anything for which we have not an inherited ability. This seems to me to be not great science but commonplace.

And now perhaps also environment. Environment does not matter in this regard. We try to interfere in the right way and impress the child in such a way that he becomes trained in social adjustment and coöperation, but we are not wholly sure if our interferences really work rightly. We must look beyond this argument and adjust our interference and coöperation. We must look for the results and we must interfere in the results. And on this point we say that it can only be done by education: education in the broadest sense. Therefore such an explanation as this of to-day means putting back education on its right throne again, against all other views, against the views of heredity and environment. We are responsible, we educators. And we say that ability to coöperate *can be and must be trained.* It is as with a subject like history or geography. If a person is not *trained* in geography, and would solve a geographical question, you will see that he fails.

There is another aspect. As long as a person is not tested in regard to his ability to coöperate, for example through being in a favourable situation where he is not confronted, you cannot be absolutely sure in regard to his degree of coöperation. On this point we begin to understand why, for instance, in hard times people reach the limit of their ability to coöperate. Suicides increase, crime increases, the neuroses and psychoses increase, because the ability of coöperation stops at this point; it does not go further. If a person is tempted too much, so far as we can see in our time there are many persons who, if they were tempted, would show that socially they were rightly prepared. Therefore we say always that the failures reach a certain point which is the crucial point. It is their test examination. At this point it appears that their preparation for social adjustment is not rightly accomplished.

I have touched on the problem of training. T mother begins, the father has to continue, and th other children and circumstances from You can see how prejudices may hinder the development of social adjustment, and how poverty, misery, sufferings, imperfect organs, and sickness, may make child more interested in his own person than in others. The greatest part of failures we find springing pampered *dependent* children because these are more interested in themselves. They want exploit others, to appropriate the others. want to utilise the coöperation of others, and they do not feel strong enough themselves in facing certain social problem. When they have to face problem it appears in their whole behaviour attitude that they do not feel prepared. They not feel able—and so they express it—to solve problem. I have called this the *inferiority plex*, and you find many failures have failure to solve the social problems. We now why they do not feel able; because they not trained in coöperation, they have not social interest. Now the child's inferiority may be like a stimulus. But the dependent do not try to compensate this feeling by feeling while. They have *excluded* this way of coöp and therefore they are looking for a goal of superiority where there is a feeling of being than others; for instance, the urge to others, to kill others, to deprive others, to others unhappy, and torture others, to others, to resent them, and so on. You find it in the causes of failure I have mentioned, that they striving for a superiority, a personal which is not useful for the whole of mankind. this goal of superiority they do not find in the p of coöperation. And so, may we not say that on points we can prove that the meaning of life must for the greatest part coöperation? And now have to make it living.

LANCASTER INFIRMARY.—Lady Ashton, widow Lord Ashton, who laid the foundation-stone of this in 1896, recently opened extensions, including a ward, a children's ward, and additions to the nurses' which have cost £25,000. A war-time building, erected munition workers, is shortly to give place to wards, and the entire scheme will cost £75,000.

HEREFORDSHIRE ISOLATION HOSPITALS.—After comprehensive survey of the isolation hospital dation in Herefordshire, the county medical Dr. Peter Lowe, reports that the present system small fever hospitals run by various authorities, others contract with neighbouring bodies, is and recommends its supersession by the erection of central hospital managed by a joint hospital board. hospital belonging to the borough of Leominster is condemned. It is a small wood and iron building, in of painting and repairs; the water-supply is from a used by neighbours, and there is neither a telephone, mortuary, nor a disinfection room—an old cab is a disinfecting chamber. Hereford city isolation is of wood and corrugated iron; the scarlet fever antiquated and decayed, and no system of lighting installed. The ambulance is a horse-drawn cab, in only children can be placed in a recumbent position. Leominster and Wigmore isolation hospital also has ancient cab as ambulance, but there is neither horse harness. There is no indoor sanitation, no warming, the lighting is by oil lamps. The report and rec have not yet been considered by the county council.

TREATMENT OF CANCER OF THE BREAST.

A CLINICAL REVIEW OF 150 CASES.[*]

By L. Martindale, C.B.E., M.D., B S. Lond.,
SENIOR HON. SURGEON, NEW SUSSEX HOSPITAL, BRIGHTON;
HON. SURGEON, MARIE CURIE HOSPITAL, LONDON.

Comparatively few cases of mammary cancer re treated in this country even with prophylactic ray therapy, or with radium for recurrences, and therefore felt that a review of a series of 150 cases, a very large percentage of which I have used ost-operative radiotherapy, might be of value. hope to prove that the results of surgical operation this disease could be improved if all cases were eated with adequate and early post-operative diotherapy.

The low operative mortality—about 1 per cent.—d the excellent immediate results—or very high ree-year survival rate—probably account for the that treatment of cancer of the breast has remained long exclusively surgical. The high operative ortality and poor end-results in cancer of the rvix uteri, on the other hand, have caused a growing terest in radiological methods. The operation for ncer of the breast has reached probably its final age of development, while radiotherapy is in its fancy and is dependent on the research of the ysicist and improvements in apparatus, necessitating change of technique and plant every few years. evertheless, prophylactic post-operative X rays, d X rays or radium or both for recurrences and operable cases are now advocated by many authoties, notably Sampson Handley[1] in England; arnekros, Seitz, Wintz,[2] Doederlein, Buchholz[3] and olfelder[15] in Germany; Béclère and Regaud[4] in ance; and in America Burton Lee[5] of the New ork Memorial, Pfahler and Parry,[6] of Philadelphia, d. Harrington[7] of the Mayo Clinic. I have myself sited clinics in Frankfurt, Erlangen, Freiburg, rlin, Dresden, Munich, Paris, New York, Baltimore, iladelphia, and Rochester—most of them more an once—in order to follow up the changes and odifications in technique.

Radical Surgical Treatment.

Since, according to most authorities, untreated ses survive for two and a half to three and a half ars, the many hundreds of statistics given on a three-ar survival basis must surely be unsatisfactory. evertheless, the consensus of opinion is at present in vour of a preliminary radical operation in all erable cases. Lane-Claypon's[8] figures show the periority of a complete over an incomplete operation. ly 23 of her 2006 cases had had post-operative radioerapy, but this superiority is more marked in the ses treated by surgery alone. Even more than the nature of the operation, the results depend the stage the disease has reached, and this probably counts for the apparently excellent results sometimes tained in early cases by incomplete operation. riously enough, as has been pointed out by Pfahler d others, the kind of operation and the stage of the sease are more important factors than the type of owth.

The stages of development of the modern operation e interesting and have an indirect influence on the chnique of post-operative radiotherapy. Halsted,[9] of Baltimore, in 1894, first advocated the removal of the axillary glands and the pectoral muscles, and later also of the supraclavicular glands. He made a point of the necessity of removing these in one piece, making a very wide removal of skin and leaving the wound to heal by granulation. Stiles, of Edinburgh, pointed out that both Halsted and Gross removed an unnecessary amount of skin; but advocated a wider removal of the outlying breast lobules and circummammary fat, to ensure ablation of the cancerous lymphatics so frequently found throughout the organ. In this he won the support of Prof. Watson Cheyne, whose first paper on the subject was published in 1894. Rodman,[10] of Philadelphia, in 1908 introduced a further modification in technique, but to Sampson Handley[1] we owe perhaps our greatest debt for his operation founded upon epoch-making pathological researches.

Handley asserts that cancer spreads in the parietal tissues by permeating the lymphatic system like an invisible annular ringworm. The growing edge extends like a ripple in a wider and wider circle, within the circumference of which healing processes take place, so that the area of permeation at any one time is not a disc but a ring. The spread of cancer in the parietal tissues is, in fact, as truly a serpiginous process as the most typical tertiary syphilide. The ideal surgical operation, therefore, is one which, even in the early case, provides for the wide removal of the skin of the affected breast, the still wider removal of the deep fascia, the removal of the pectoral muscle or muscles, the axillary glands, and the fat en masse. Any exploratory or two-stage operation is to be avoided, for incision into the growth has been shown by Gye and others to be the surest means of disseminating carcinomatous cells. If an exploration has been made it should be followed immediately by the complete operation. Carter-Braine, and Massie report 722 cases of carcinoma with 80 per cent. three-year survival-rate without recurrence, provided that operation follows clinical or biopsy diagnosis immediately. If there is an interval between exploratory and radical operation the survival-rate is reduced by 13 per cent.

Another point of interest is that the lymph glands, though ultimately they may become infective foci, for a long time delay the progress of cancer cells. They act as mechanical filters, and there is evidence that, for a time at least, they exert a destructive action on the cancer cells which reach them, and only succumb to the invasion after a prolonged resistance. (Incidentally this is the chief reason why the supraclavicular glands are not irradiated unless they are already invaded by cancer, and why the practice of their routine removal has been abandoned.)

The peculiarities of metastatic distribution are in themselves sufficient to show that cancer cells which gain access to the blood are usually reduced to impotence. The opposite axillary glands, the opposite breast, or the inguinal glands are never found cancerous early in the case, as should occasionally happen if cancer cells can reach them embolically from other lymphatic areas. Some cases show invasion of the axillary glands on the side opposite the primary growth, probably indicating that permeation has extended well over the middle line and that cancer cells have thus penetrated to the trunk lymphatics which drain into the opposite axillary glands.

Case Records.

To obtain an accurate record of my cases I devised some years ago a special protocol which I have found useful, both for accurate note-taking and the necessary regular follow-up. I find that my youngest patient was 26 and my oldest 81½ years—64 per cent. of all patients being between the ages of 40 and 60. The average duration of symptoms before the patients applied for any form of treatment was 11 months, which indicates the actual delay in seeking advice and gives some idea of the advanced stage of the disease. The symptoms and physical signs most often complained of were a lump in the breast (80 per cent.), much less often a feeling of discomfort, retraction, or discharge from the nipple, ulceration, or a stinging sensation. In only 3 per cent. was there a history of injury. This is apparently a low figure, as some observers record a history of injury in some 14 per cent.

---

[*] Based on a paper read before the London Association of the dical Women's Federation.

I have treated 120 cases with post-operative X rays or radium or both, 21 cases with surgery only, and 9 cases with radiotherapy only. I have included all cases of breast cancer I have treated: 86 cases in which I performed radical operation myself, as well as 31 cases which have been operated upon by other surgeons and referred to me for radiotherapy, and 24 cases in which incomplete or palliative operation was performed. (Table I.)

SURGICAL TREATMENT.

In my own series of cases I have adhered to a modification of Halsted's technique. I make an elliptical incision, including the nipple and a wide margin of skin outside the area of the growth itself; I remove the sternal portion of the pectoralis major, cutting through the humeral end of the muscle as close to the bone as possible. In some cases I remove the pectoralis minor as well and in every case a very wide area of fascia, well over the mid-sternal line, to the clavicle above to the latissimus dorsi behind, and to the rectal sheath below. I then call for a high stool and sit comfortably down, and dissect out the axillary glands and fat, leaving as clean an axillary vein, artery, and nerves as possible.

I use several pints of warm 1–4000 corrosive sublimate to wash over the raw area, having kept the flaps the whole time as clean and protected as I could with thick warm wet mattress swabs. I put in a biggish drainage-tube through the outer up into the axilla, and unite the flaps with 8 or through-and-through silkworm gut sutures, protect by thin rubber tubing, with Michel's clips betw For the first week I encourage the patient to ke her arm out at right angles on a pillow, using th hand as much as she comfortably can. On the ten or twelfth day I let her sit up if she is inclined, but do not hurry her out of the nursing home or hospital she remains until the nineteenth or twentieth day.

The results of surgical operation are seen in Table I They are quite excellent as regards primary operat mortality and three-year cures—but if one is enough to follow up the cases for 10 to 15 or m years they are found to leave much to be desire Sampson Handley says that during the last 14 more years every case of breast cancer upon which has operated has received a prophylactic dose X rays, and that in his series of cases recurrence the skin has been almost absent, three of the cases in which it took place occurring among the percentage of cases which had escaped the prophylactic course of X rays; this has also been own experience.

SURGERY AND DEEP X RAY THERAPY.

In my own series of treated cases of cance the breast I find that I have used pre- or operative radiotherapy in some 120 out of 150 It is difficult to arrive at a correct assessment its value, because it is only in a comparatively number of cases that I have been able to give can be called really adequate X ray tre namely, at least one pre-operative treatment 14 before, and post-operative prophylactic treat starting two to four weeks after operation. Table II. I have compared my results with those surgery only, as well as with untreated cases and survival in healthy subjects, and in Table III. I h shown other people's results.

Pfahler and Parry,[6] in a recent statistical study radiation therapy in 939 cases of cancer of the bre point out that the average time intervening betw operation and X ray treatment in 646 cases unfortunately as long as 15 months. My own av interval was also unfortunately 11 months. I believe with Soiland[11] that patients should be g pre-operative as well as post-operative treat and that the latter should be started as soon as or three weeks after operation. Pre-operative tion is based on the theory that such tr devitalises the cancer cells, and therefore makes less liable to grow if re-implantation or tran occurs during the operation. This devitalisation cancer cells is a recognised effect of irradiation, clinically and experimentally. Murphy, at Rockefeller Institute, and others have details of their research into this subject. Gye shown that incision is one of the surest means disseminating carcinomatous cells, and such a of therapy, it is assumed, will reduce mitosis of malignant cells sufficiently to render them innocu In my own series I was able to give adequate therapy in 68 cases and inadequate in 52. I h had to include under "adequate radiother cases which have had their first X ray ment as long as 6, 12, or more weeks after tion, and only three cases in which pre-operat treatment was given as well. Even with this inte the results are good, and more than justify operative prophylactic therapy, although I h little doubt that earlier irradiation would show better results. Unfortunately, at the present ases are apt to be referred to the radiologist only hen an inadequate operation has been performed. In 40 only of these cases have I been able to give dequate X ray therapy after radical amputation, nd these I have shown in Table IV. In working out e end-results, which are seen in Table III., it will noted that adequate X ray therapy has improved e three-year end-results by 23 per cent. in I.P. and C. cases and 44 per cent. in II.P. and II.C. cases; e five-year end-results by 23 per cent. in I.P. and C. cases, and 40 per cent. in II.P. and II.C. cases; and e 10-year end-results by 4 per cent. in I.P. and C. cases and 69 per cent. in II.P. and II.C. cases. e 4 per cent. is not a correct figure, as two deaths t of three were not due to cancer. This is surely questionable evidence of the efficacy of such atment.

ABLE II.—SHOWING PERCENTAGE OF SURVIVORS AFTER OPERATION ACCORDING TO STAGE OF DISEASE, AS COMPARED WITH UNTREATED CASES, LIFE TABLE, AND MY OWN CASES TREATED WITH RADICAL AMPUTATION FOLLOWED BY ADEQUATE X RAY THERAPY.

DEQUATE RADIOTHERAPY IN CASES OF INCOMPLETE OPERATION.

Of these I have in my series 14 cases; 11 are alive d well, but 4 of these are too recent to be of lue in any table of statistics. Ten cases were treated between 1914 and 1927. Of those alive and well No. 1 was treated 12 years ago and No. 49 7 years ago.

CASE I.—The patient was a married woman aged 51, without children. She had noticed the lump a few weeks before coming to me in 1917. I performed a simple amputation, as the patient took the anæsthetic very badly. I began treating her with X rays three weeks later. Six months later the axillary glands on both sides became hard and large. With further X rays, which I continued for two years, these became normal, and the patient has had no further recurrence and is extremely well.

CASE 49 was also interesting; she came to me in 1923 at the age of 46. She was a widow with two children, and had noticed a lump for the last three years. Although she was, technically speaking, inoperable as the axillary glands on both sides were enlarged and hard, I advised and performed a palliative simple amputation, starting prophylactic X ray therapy three weeks after and continuing it at intervals for two years. The glands are now normal, and there has been no sign of recurrence (seven years after.)

INADEQUATE RADIOTHERAPY.

I have carried out inadequate radiotherapy in 43 other cases combined with radical operation, and in 9 cases combined with incomplete operation. In the

greater proportion of cases it was performed for recurrences in patients who had not been treated with prophylactic radiotherapy, and in other cases it was given for the relief of pain.

DEEP X RAY THERAPY ONLY.

I have used this only in five cases, when operation was contra-indicated by the condition of the patient. One of these I lost sight of after two X ray treatments. Of the other four, two lived three years, one four, and one five years after the beginning of treatment.

In my cases I have included all five types—namely:

(a) early without apparent secondaries;
(b) advanced with secondaries (i) axillary; (ii) supraclavicular;
(c) recurrence after operation (i) local; (ii) distant.
(d) primary inoperable.
(e) primary operable, but operation refused or contra-indicated.

PATHOLOGICAL REPORTS AND RADIOLOGICAL TECHNIQUE.

The pathological reports, of which I have records all but a small percentage of cases, are classified under the following headings:—

(a) Spheroidal-celled (mainly fibrous); (b) spheroidal-celled (mainly cellular); (c) "carcinoma," type not stated; (d) Adenocarcinoma; (e) columnar-celled; (f) colloid cancer; (g) Paget's disease; (h) mixed carcinoma; (i) sarcoma; (j) no pathological report obtainable.

I have, of course, exact notes of the technique used in each case, but my experience has been that of others—namely, that the success of treatment depends more on the type of case when first treated and the shortness of time between the operation and radiotherapy than on the type of growth, marked radiosensitivity being no criterion of the ultimate ease of cure.

The actual technique has been changed with the change of type of the X ray installations used. I have tried to keep up with the modern development in apparatus.[15] In 1922 I adopted a modification of the Erlangen technique, as worked out by Seitz and Wintz,[2] using a voltage of 136,000 and giving only one or two massive treatments. In 1929 I further modified my technique by using the Stabilivolt. Briefly, my present technique is this:

The patient is prepared as for a minor operation; an aperient is given the day before if necessary, and she takes only a light breakfast. The part to be irradiated is mapped out with a skin pencil. If the supraclavicular glands are found not to be affected they are carefully avoided. If the axillary glands which have been removed are found to be carcinomatous the axilla is included.

In my early cases I rayed the patient with her arm held at right angles to her body; in my later cases with the arm comfortably to the side. My present technique for prophylactic irradiation is one big field anteriorly, the focal distance being 40–50 cm. I use either 0·5 Cu. +2 al. or 1 Cu. +2 al. filter, a voltage of 150–180,000, 3 ma. in the secondary current, a Coolidge or A.E.G. tube of a unit skin dose of approximately 12·15 min., and a depth dose of 18·6 per cent. In every case I warn the patient to be careful not to apply

TABLE IV.—FORTY CASES OF THE AUTHOR'S OWN SERIES IN WHICH RADICAL OPERATION WAS FOLLOWED BY ADEQUATE X RAY THERAPY—(*continued*).

Case.	Year.	Age.	Pregnancies.	Operation.	Type of case.	Pathological report.*	Time between operation and radiotherapy.	Radiotherapy.	Time between operation and recurrence.	Recurrence.	Duration of life after operation.
83	1918	63 M	2	Simple amp., rt., 1918; radical, lt., 1926.	A.	1918: Chronic mastitis only. 1926: Dense fibrous tissue with areas of acute inflammatory reaction, but no malignancy. Glands almost completely replaced by spheroidal-celled carcinoma.	6 wks.	A1—1, B, C2.	—	None.	12 yrs. (1st op.) 4 yrs. (2nd op.) (S.L.).

soap or any irritant or great heat to the skin for some weeks, and to use an emollient cream (such as cera. alb. ʒiss., cetaceum ʒiss., Ol. Olivæ ℥ix., and aq. destil. ʒiiiss.) for at least a week.

This treatment I like to repeat in six weeks.

CASTRATION.

Hans Meyer, Polano, Rosenberg, and Wintz and his disciples advocate, in addition to X ray treatment of the breast, the induction of an artificial menopause by means of deep X ray therapy. They maintain that every menstruation as well as pregnancy is accompanied by changes in the activity of the mammary gland. In some 38 per cent. there is increase in the size of the gland just before the period; there is actual secretion in 6 per cent. of parous women and in 1·5 per cent. of nulliparous women—due probably to the action of an ovarian hormone. They assert that activity of the mammary gland is to be avoided in every carcinoma of the breast. Wintz reports several cases in which, for instance, a pregnancy has been accompanied by recrudescence of malignant growth in an apparently quiescent radiated breast. Some years ago Stanley Boyd published a series of cases in which he had performed double oöphorectomy in cases of breast cancer. Sir Holburt Waring[17] also performs this operation in inoperable cases, and has observed reduction in the size of the tumour in 20–30 per cent., only to be followed by recrudescence three years later.

The technique is simple, and with my own apparatus I can now ensure a menopause in one, or at the most, two treatments of one and a half hours each.[18] I have, however, never been able to persuade myself that there is sufficient evidence of its value in cases of breast cancer to justify the extra irradiation involved, and I have therefore never carried it out for the treatment of this disease.

RADIUM TREATMENT.

In recurrent nodules occurring over sternocostal articulations, or over or near the scar, in some primary cases, and for supraclavicular glands, there is perhaps no better treatment than radium. There are three methods of applying radium in cancer of the breast:—

1. Superficially, by means of batteries of needles enclosed in applicators of platinum or silver and further screened by sheet rubber 1 mm. thick; or by fixing the needles on to a mould of Columbia paste (a mixture of wax and sawdust). It is important to calculate the dose of radium very exactly to ensure a homogeneous radiation.
2. By needles containing radium distributed evenly in such a way that 1 mg. radium element is contained in each cm. of length and suitably screened, buried into the tissues at even distances, and left in situ a certain number of hours.
3. At a distance, using the beam of rays from a mass of radium contained in the so-called "bomb." In this case by means of cross-fire—viz., introducing the rays through different areas of skin, a larger dose can be applied to the depth of the tissues without fear of too much skin reaction.

Geoffrey Keynes (St. Bartholomew's Hospital)[16] has recently published, in his Hunterian lecture, a series of 109 cases in which he has used radium only for carcinoma of the breast, and claims that even for early cases radium is the method of choice. Failures are probably due to an insufficiently long exposure or to treatment of an insufficient area. Sir Lenthal Cheatle insists on the widespread occurrence of microscopic changes in the mammary gland which contains a carcinoma, apart from the lymphatic infiltration. Keynes therefore advocates the wide application of radium—namely, beneath the breast, beneath the pectoral muscles, in the axilla, and under the costocoracoid membrane above the clavicle, and in the upper three or four intercostal spaces—for a period of 168 hours (7 days). The main principle is prolonged exposure to a relatively small dose of radium and the application of the needles in such a way as to avoid puncturing the actual growth itself.

The results are, briefly, a change in the size of the tumour within two or three weeks. By the end of two months the tumour may, in favourable cases, shrink to half its original size, and disappear in three to six months. If, by the end of six months, the growth is stationary, a second application of radium may be given or the residual tumour may be excised. For recurrences—especially those which are so common over the costosternal region—radium in adequate doses seems to be infallible. In my own short series of radium cases they have all completely disappeared, and so far there has been no recurrence.

SURGERY, USING THE DIATHERMY OR ENDOTHERMIC KNIFE.

To prevent the actual dissemination of carcinoma by operation—a condition occasionally seen, the secondary growth appearing in the skin and at a distance apparently even more quickly than if no surgical treatment at all had been undertaken—several surgeons of late have used the diathermy knife instead of the ordinary scalpel. I have not myself used this method in a radical amputation of the breast, although I have done so for recurrent nodules in several cases and for seven cases of primary carcinoma of the vulva. Indeed, there is much to recommend it, and the newest type of diathermy apparatus is so devised that the actual cut is cleaner and causes less coagulation and charring of the tissues; the wound therefore heals by first intention.

Conclusions.

(*a*) For successful treatment in operable cases we have to ensure early treatment, when the disease is still localised to the breast, by

(1) *radical operation* removing in one piece the breast, fascia, pectoral muscle or muscles, fat and glands; and, in addition, most important of all,

(2) *adequate X ray therapy* beginning not more than three to seven weeks after operation, and lastly,

(3) in all advanced cases three or four needles of *radium* placed along the third, fourth, fifth, and sixth intercostal spaces in the hope of destroying cancer cells in the internal mammary group of lymph glands and two or three needles in the infraclavicular region and axillary region.

(*b*) *For inoperable cases* radium and X ray treatment according to the kind of recurrence. In those cases in which reduction in the size of a recurrent nodule takes place and it becomes freely movable, surgical eradication, preferably by the endothermic knife, may be carried out within 8–10 weeks. In those cases in which recurrence and metastases produce pain and discomfort, radiation, according to Bloodgood, is the only method that offers any relief at all.

The most important factor of all in ultimate success is the early treatment of the disease. As symptoms are unfortunately often absent until the tumour is well developed, probably the only way to ensure early treatment would be to establish cancer clinics all over the country, and circularise the fact amongst women of all classes who have passed the age of 35, urging them to be regularly overhauled every six months by a competent specialist. Only in some such way as this are we likely to reduce the cancer incidence.

ANTHRACOSIS, SILICOSIS, AND TUBERCULOSIS IN COAL-MINERS.

By S. Lyle Cummins, C.B., C.M.G., M.D. R.U.I.,

DAVID DAVIES PROFESSOR OF TUBERCULOSIS, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF.

The name "anthracosis" has been loosely applied to describe the black pigmentation so often found in the lungs of city dwellers and of persons exposed, either in town or country, to the smoke of coal fires. It was first used, however, in a more restricted sense by its originator, Dr. T. M. L. Stratton (1838), who coined the word to describe the "black lung" of coal-miners, and it seems desirable to retain the word for this condition only.

As long ago as 1813, George Pearson had demonstrated clearly that the black pigment accumulated in the lungs of city dwellers was carbon. The fact that the anthracosis of coal-miners may present a marked accumulation of silica as well as of carbon in the lung tissue was first proved by E. H. Greenhow in 1869, this observer publishing his chemical analysis of a coal-miner's lung in that year and demonstrating the existence of 30 per cent. of silica in the lung ash after incineration. Tattersall in 1926 called attention to the occurrence of silicosis, as proved by radiological and clinical findings, in a series of South Wales coal-miners who had been exposed to silica dust while working with drills in "hard headings."

That radiological evidence of a lung fibrosis indistinguishable from that of silicosis is to be found, not merely in those coal-miners employed in "hard headings" but in a large proportion of middle-aged coal-miners working at the "coal face" only, has been demonstrated in the course of a recent "radiological study of certain groups of 'industrially healthy' South Wales coal-miners," carried out by members of the medical staff of the Welsh National Memorial Association, and published in the Association's eighteenth annual report, 1930; while the findings of Collis and Gilchrist (1928) in coal-trimmers suggest that somewhat similar appearances may be found in X ray films of the lungs of persons other than coal-miners exposed to high concentrations of coal dust.

The writer has been engaged for some years in an examination of the pathological and histological characters of the lungs of coal-miners. In 1927 he published a brief description of his findings in one of the "hard heading" workers of Tattersall's series, together with a chemical analysis of the lung ash carried out by Dr. J. Pryde, of the Physiology Department, Cardiff, showing that a marked increase in perivascular and peribronchial lung fibrosis and blockage of lymph channels was associated in this case with a percentage of silica much in excess of that found in the lungs of a non-anthracotic male adult, dying of pulmonary tuberculosis, examined as a control.

Since that date, the writer and Dr. A. F. Sladden, of the Beck Laboratories, Swansea, working on a series of lungs from South Wales coal-miners, have been able to carry their observations further and to link up their pathological and histological findings with chemical analyses carried out, at first, by Dr. Pryde, and Mr. C. A. Seyler, of Swansea, and later, through the good offices of the Mines' Department, by Prof. R. V. Wheeler and Dr. F. V. Tideswell, in the laboratory of the Safety in Mines Research Board at Sheffield. The results of this investigation have recently been published (1930), and need not here be referred to in detail.

Anthracosis a Dual Condition.

The only point to which it is desired to direct attention is the fact, which comes out clearly from our investigations, that the anthracosis of coal-miners is a dual condition in which the retention of coal dust in the lungs is associated with and, in all probability, due to, a state of diffuse or nodular lung fibrosis and lymph blockage indistinguishable from that found in the silicosis of gold-miners on the Rand and of those engaged in the "refractories" industries in this and other countries.

Not only are the pathological and histological appearances similar but the chemical analyses reveal, in the lung ash, percentages of silica of the same order as those found by J. McCrae (1913) in the lungs of Rand gold-miners; while the examination of lung sections with "crossed Nichols" shows the same accumulation of doubly refractile particles described by Watkins-Pitchford and James Moir (1916) in silicotic lungs at Johannesburg.

Moreover, in our coal-miners' lungs, the extent of the fibrosis and lymph blockage, the percentage of silica in the lung ash, the number of doubly refractile particles visible in the sections, and the degree of clinical pulmonary disease recorded prior to death are all found to vary directly with the amount of exposure of the individual to silica-containing dust, being greatest in those with an industrial history of work in "hard headings" or as "repairers," although often quite marked in coal-miners with no history of work other than at the coal face.

In the case of the "hard heading" workers and "repairers," the source of the silica dust leading to this silicotic fibrosis is obvious. In the case of other types of coal-miners, it is less clear, and to the elucidation of this problem of the source of the silica risk in coal-mining, further research is urgently necessary. But, for the moment, it suffices to say that, in the coal-mining industry, a risk of silicosis exists, that is as great, in the case of certain categories of coal-miners, as the risk of silicosis in gold-mining, tin-mining, and the "refractories industries," and that, in a large proportion of old coal-miners of other categories less intimately in contact with stone dust, there is radiological, pathological, and chemical evidence of a condition indistinguishable from pulmonary silicosis.

Resistance to Tuberculosis.

One characteristic feature of silicosis, however, is absent in the case of coal-miners—the increased liability to tuberculosis. In fact, there is much reason to think that coal-miners, far from being specially liable are, on the contrary, exceptionally resistant to pulmonary phthisis. Haldane (1923), dealing with this subject, speaks as follows: "The diminished relative liability to phthisis among coal-miners has existed for generations. In the available statistics for 1849–53 it is no less marked than now." Collis (1922) expresses the same view. "The incidence of phthisis among coal-miners, not only in Great Britain but in other countries, is lower than that found in other occupations with the exception of agriculture." Sir Thomas Oliver (1916) writes as follows: "The comparative freedom of the coal-miner from tuberculous phthisis is not confined to this country alone. According to a census of the United States, pulmonary consumption caused 10·6 per cent. of all deaths among miners and quarrymen as against 16·2 per cent. for all occupied males."

That the contrast between coal-miners and other workers in silica dust is a striking one will be appreciated from the following figures extracted from the Registrar-General's Decennial Supplement, 1921.

Mean Annual Respiratory Tuberculosis Mortality by Age-Groups per 100,000.

Age	16–	20–	25–	35–	45–	55–	65–	70–
All occupied and retired civilian males	69	136	133	160	166	150	114	64
Coal-hewers and getters ..	40	78	80	110	114	139	147	47
Metal grinders	61	136	237	551	1149	1246	761	383
Tin and copper miners ..	—	91	746	1520	1744	2632	517	680

There can be no doubt whatever that silicosis, when due to exposure to silica dust without coincident exposure to coal dust, is accompanied by a terrible liability to tuberculosis in late middle age. There is no need to labour this point, which is known to all who have studied the subject.

With regard to coal-miners and their fortunate exemption from this risk, we are driven to the alternative of believing either that the lung fibrosis from which they suffer is not due to silica dust or else that there is, in the industry, some factor peculiar to coal-mining and capable of neutralising the risk of tuberculosis to which silicotic coal-miners would otherwise be exposed.

As already indicated, there is no appreciable difference between the pathological, chemical, and radiological findings in anthracosis in South Wales and silicosis on the Rand except the added accumulation of coal dust in the former; and it would, therefore, appear unreasonable to suppose that the lung fibrosis of coal-miners is essentially different from that called silicosis in gold-miners. If this much be conceded, we are forced to the conclusion that there is some factor peculiar to coal-mining which is inimical to the development and spread of tuberculosis in the lungs. Oliver believes this factor to be "the better ventilation of the coal-mines, the air of which, as it passes onwards through the mine, becomes rid of bacteria and reaches the miner at his work in a purer state than the air we breathe in the streets of a large town."

This theory appears hardly tenable when it is recalled that the ventilation of the Rand gold-mines is at least as good as that of the coal-mines of South Wales; nor is it consistent with the fact that the coal-miner, who, after all, lives the greater part of his life above ground and is equally exposed with the rest of the population to home contact with infection, suffers less from tuberculosis, in every age-group except one, than "all occupied and retired civilian males."

Haldane, in the paper already quoted, says: "It is difficult to resist the conclusion that in some way the inhalation of dust in coal-mines tends to prevent phthisis," and he appears to think that the beneficent action of coal dust is due, in part at least, to a power of stimulating "the physiological process of dust excretion" or, in other words, of helping on the process of carrying the injurious silica dust out of the lungs in the interior of phagocytic cells. This idea was thought to gain support from the experiments of Mavrogordato (1918) on the dusting of animals with silica dust and coal dust in varying combinations. It does not, however, explain the mechanism by which silica dust, when inhaled alone, gains access to the lung tissues. In the writer's opinion, it is only by transport in the interior of phagocytes that it can pass from the alveoli into the interstices of the pulmonary tissue, a consideration which implies active phagocytosis of silica particles. Incidentally, these particles can be located inside phagocytes by the examination of stained sections alternately by direct and by polarised light. Kettle (1930), in a recent paper, opposes this theory of the stimulation of the phagocytosis of silica particles by coal dust, and quotes Gardner to the effect that "quartz produces the greatest degree of phagocytic activity of any dust he has investigated."

To the writer, his own observations into the anthracosis of coal-miners suffice to convince him that the simultaneous inhalation of silica dust and coal dust over long periods leads to a blocking up of lymph drainage by silicosis, and a resulting retention of the coal dust in the lungs rather than to any increased elimination of the one dust with or through the other, a belief which is supported by the experiments of Mavrogordato (1922) in the exposure of guinea-pigs first to silica dust and then to coal dust. It is clear, in any case, that the theory of stimulation of the "physiological process of dust excretion" does not suffice to explain the relative freedom of coal-miners from tuberculosis, since they are by no means free from silicosis.

It comes to this: that the only outstanding histological and chemical difference between the silicotic and the anthracotic lung is the retention of excessive coal dust in the latter; and that the only outstanding epidemiological difference between pulmonary silicosis and anthracosis is the absence of tuberculosis liability in the latter.

This being so, it is natural to associate the presence of accumulated coal dust in the lung with the relative exemption of coal-miners from a high tuberculosis mortality and to seek in the one phenomenon an explanation of the other.

The "Protective Influence" of Coal Dust.

The theory that coal dust affords some degree of protection against pulmonary tuberculosis has been put forward by numerous investigators. Wainwright and Nichols (1905) give interesting statistics in support of this contention from Scranton in the United States, and add a valuable summary of the views of German workers on the subject. They quote Goldman (1905), who holds that coal dust has an antiseptic action, and Arnold (1885), who thinks that "if there is any action, it is due to the fact that the deposits of dust prevent the spread of the poison," and does not believe in a direct bactericidal effect of carbon on the tubercle bacillus. Their own experiments in vitro failed to show any antiseptic action by carbon but, in a limited number of in vivo experiments in the induction of experimental tuberculosis in guinea-pigs previously rendered anthracotic by repeated exposures to coal dust, they found that there was, in the dusted animals, an absence or limitation of the tuberculisation of the lungs as compared with the non-dusted "controls," a finding which was, however, less definite in a subsequent series of experiments, and which Mavrogordato (1922) has failed to confirm. "Our opinion," they conclude, "is that the coal dust in the lungs does exert a protective influence against the tubercle bacilli, and that it is due to the stimulating effect of coal dust on connective tissue growth." Their conclusion in favour of a "protective influence" is probably right but, in view of the much greater power of silica dust than coal dust to stimulate the formation of connective tissue and its known association with an increased tuberculosis liability, their theory to account for this protective influence is almost certainly wrong.

There appear to be valid arguments against the three main theories so far suggested to explain the alleged protective influence of coal dust against tuberculosis. Neither the physiological concept of an adjuvant action to the phagocytosis of silica particles, nor the theory of an antiseptic action, nor that of a stimulation of connective tissue by the carbon particles will bear close investigation. There remains the possibility that carbon may owe its "protective influence" to its power of adsorbing toxic substances. The adsorptive power of finely divided carbon for colloidal substances such as dyes is well known, and those familiar with the defensive side of gas warfare will recollect the astonishing efficiency of the carbon layer of the "box respirator" in adsorbing poisonous gases.

As to the adsorption of the active principle of tuberculin by carbon, conflicting opinions have been expressed by different observers. Long and Seibert (1925) failed to demonstrate any adsorption of the active principle of tuberculin by animal charcoal, and Jousset (1915) is quoted by Boquet as having failed to obtain any adsorption of tuberculin with "le noir Girard," the type of carbon used by him in his experiments. Boquet, Nègre, and Valtis (1928), on the other hand, were able to show clearly that a very finely divided charcoal, "norit supra," is highly potent in adsorbing from tuberculin the constituent on which its activity depends. Dorset, Henley, and loskey are quoted by Tytler (1930) as finding that adsorbents carrying a negative charge, including charcoal, largely or completely abolish the activity of tuberculin.

The writer has put this question to the test, and has been able to prove beyond any question that the finely powdered dust of anthracite coal is capable of adsorbing a large proportion of the active principle from old tuberculin diluted with normal saline solution. The active principle of tuberculin, as also of tubercle bacilli, that is to say, the part which evokes allergic reactions in hypersensitive tissues, has been shown by Long and Seibert in America and by Tytler (1930) in this country to be a protein. It is probably this same active principle which leads to the allergic reactions around tuberculous foci, reactions which, when excessive, lead on through inflammatory hyperæmia to necrosis and death of tissue. It is not unreasonable, therefore, to assume that the presence of large quantities of carbon particles in the immediate vicinity of tuberculous foci might, by adsorbing the products of the growth and destruction of tubercle bacilli, go far to prevent or diminish the inflammatory phenomena which constitute tuberculous disease.

It is worth noting that carbon particles and tubercle bacilli inhaled into the lungs are dealt with by the same type of phagocytic cell, the monocyte, and carried through the same channels along the lung lymphatics, to the lymph nodes at the hilus; or, if their progress is arrested by the blockage of lymphatics through silicosis or any other cause, they must necessarily take the same collateral channels towards the pleura and the pleural lymphatics or accumulate in the same situations as coal dust in the lung tissue. In the case of the coal-miner, who, like other people, must often inhale tubercle bacilli, there is always certain to be a considerable amount of carbon in the immediate vicinity of such of the bacilli as may reach the lung tissues.

The power of finely divided coal dust to adsorb and inactivate a proportion at least of the active principle on which the clinical effects of tubercle bacilli depend has been established. Whether the collection of carbon particles which have accumulated in the tissues and been bathed in the tissue juices retain their power of adsorbing tubercle protein is a matter for further investigation, but the probability that they can do so is emphasised by the following facts as to the tuberculosis of coal-miners.

The lungs of anthracotic coal-miners often show tuberculous lesions of a peculiar type, characterised by an absence of the tendency to breaking down and cavitation so common in adult phthisis. Lesions of this peculiar type have recently been figured in the paper by the writer and Dr. Sladden, already referred to. The fairly frequent occurrence of these atypical non-cavitating tuberculous lesions in coal-miners is the more interesting in view of the known frequency of negative sputa in clinically tuberculous coal-miners. The writer has encountered numerous cases where the diagnosis of tuberculosis has long remained in doubt owing to a series of "negative" sputum examinations, only to be established, at last, by post-mortem examination or by a positive result from guinea-pig inoculation; and case records in his possession establish the fact that negative sputa are commoner in clinically tuberculous coal-miners than in clinically tuberculous adult males of other occupations in the same district and over the same period.

If the relative exemption of coal-miners from tuberculosis be admitted, and it can hardly be denied, then this fact must be taken into consideration along with the further fact, newly established, that a large number of coal-miners develop pulmonary silicosis in the course of years spent in the industry.

The Economic Aspect.

Apart from its pathological interest, the question has an important economic aspect. At Johannesburg the gold-mining industry pays very large sums annually as compensation to miners found to be developing silicosis; and a superficial glance at the new facts on silicosis in coal-miners might foster the idea that in England and Wales the coal-mining industry ought to shoulder the same burden. But the essential risk for which compensation is paid in South Africa is the *risk of tuberculosis* which is bound up with the silicosis of gold-miners. Dr. L. Irvine, Director of the Miners' Phthisis Bureau at Johannesburg, writes as follows (1929): "An uncomplicated silicosis may undergo prolonged and sometimes apparently indefinite arrest at any stage . . . but in the end infection tends to get the upper hand and, when this occurs, the greater the amount of original damage to the lung by silicosis, the more rapid will be the terminal breakdown. A measure of the extent of the predisposition to tuberculosis is afforded by the fact that, of all the deaths which have occurred in the two groups of cases (primary and antiprimary silicosis, S. L. C.), some 75 per cent. have been due directly to active tuberculosis."

In the case of coal-miners, this excessive liability to tuberculosis is absent. There is, if anything, a tendency to relative exemption from this disease. In this important respect, the coal-miner is in a much more favourable position than the South African gold-miner; and it is not unreasonable to lay stress on this difference at a moment when the recently elicited facts as to silicosis in coal-miners are before the public.

It would be rash to suggest that this condition of silicosis in coal-miners is free from risk. What tuberculosis is to the gold-miner, "bronchitis," perhaps, is to the coal-miner, and the high mortality from this latter cause in old colliers is, in all probability, closely associated with a life of exposure not only to coal dust but to stone dust as well.

But the word "silicosis" has come to imply a marked and formidable liability to tuberculosis, and is thus accepted in regard to "compensation" in "refractories" industries and in the gold-mining industry in South Africa. It is important to dissociate this implication from the word "silicosis" when it is applied to coal-miners.

THE NEW ABERDEEN INFIRMARY.—The controversy as to whether this building should be erected of granite or brick has at last been settled by a compromise. The material is to be granite with concrete dressings, and the cost will be about £429,000. An all-granite building would have cost £479,000, and a brick one £415,000. The medical block will be the first unit to be erected, and it is estimated that by the end of the present year the money available will, with accrued interest, amount to about £383,000.

EFFECT OF RADIATION ON MACROPHAGES.

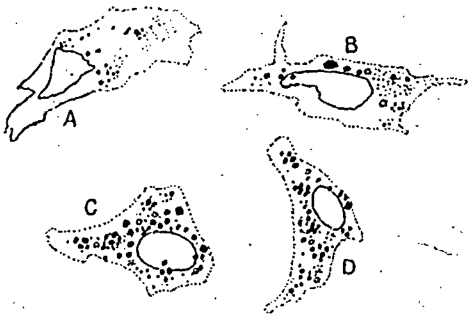
BY J. C. MOTTRAM, M.B. LOND.,

DIRECTOR OF THE RESEARCH DEPARTMENT OF THE RADIUM INSTITUTE, LONDON.

IN the connective tissue reactions associated with the disappearance of tumours produced by medical or radiological treatment macrophages are present and, in the opinion of some observers, play an important part. Todd,[1] in describing the treatment of cancer by lead selenide, insists upon the importance of "the junction tissue" as a defensive barrier, and includes the macrophage as one of its chief cell constituents. Macrophages are commonly present in both sarcomas and carcinomas; in tissue cultures they are conspicuous, since they are the first cells to migrate out into the medium. In sections of tumours which are regressing macrophages are seen filled with cell debris, and at the edge of areas showing necros they tend to accumulate. It is thus possible th macrophages pay a rôle in the disappearance tumours, and on this account the effect of radiation on them has been observed.

In order to study the direct effect of radiation, advantage was taken of the accumulations of macrophages which occur around Jensen's rat sarcoma and the mouse carcinoma T/63. These tumours were exposed in vivo for from one to two hours to β radiation, and then removed at varying periods up to 14 days. The animals were given daily inoculations of trypan-blue under the skin in order to stain the macrophages intra vitam. The tumours with the overlying skin were then removed, frozen sections cut, and counterstained with carmine. The radium applicator used was 59 mg. of radium element; area 2 × 2 cm., screen 0·12 mm. silver.

FIG. 1.



A and B, macrophages close to the radium; C and D, from beneath the tumour at a distance from the radium.

Since it takes two days to stain the macrophages, it is not possible to observe the effect of radiation during the first 48 hours. In two- and three-day specimens no change in the number of macrophages was seen. In these specimens the macrophages close to the radium between the skin and the tumour differed from those away from the radium on the underside of the tumour. These differences are shown in Fig. 1.

The deep macrophages appeared perfectly normal. The superficial radiated macrophages showed much fewer granules of trypan-blue, and also the dye was present in the cytoplasm in minute granules like dust; the nuclei of the radiated cells were shrunken and crenated.

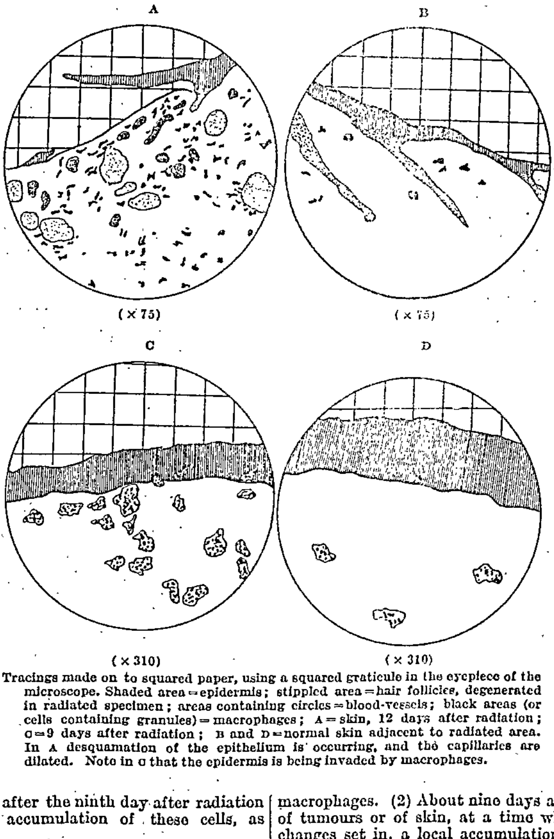
---

[1] Todd, A. T., et al.: Chemotherapeutic Researches in Cancer London, 1928. See also THE LANCET, August 23rd, p. 389.

In four-day specimens the macrophages appear less numerous between skin and tumour than in non-radiated tumours. This may, however, be due, not to an absence of macrophages, but because they have failed to take up the dye. In those containing the dye the granules are few and small. No further change takes place until about the ninth day, when the epidermal cells of the skin and the tumour cells begin to show degenerative changes as a result of the radiation; then a local accumulation of macrophages takes place.

This accumulation is not very clearly seen around radiated tumours, since they normally show infiltration with macrophages, especially in the neighbourhood of areas of necrosis. In order to show this effect of radiation more clearly rat skin was radiated. Normally the dermis contains very few macrophages but on and after the ninth day after radiation it shows a great accumulation of these cells, as shown in Fig. 2.

FIG. 2.



Tracings made on to squared paper, using a squared graticule in the eyepiece of the microscope. Shaded area = epidermis; stippled area = hair follicles, degenerated in radiated specimen; areas containing circles = blood-vessels; black areas (or cells containing granules) = macrophages; A = skin, 12 days after radiation; C = 9 days after radiation; B and D = normal skin adjacent to radiated area. In A desquamation of the epithelium is occurring, and the capillaries are dilated. Note in C that the epidermis is being invaded by macrophages.

In specimens beyond about the twelfth day the macrophages contained cell debris derived from the degenerated tumour cells and, in the case of the skin, from the epidermis, hair follicles, and connective tissue cells.

These observations are probably of importance in the treatment of cancer by colloidal preparations, such as lead and lead selenide. It is likely that the macrophages will take up these colloids, just as they do dyes, and that thus tumours will become impregnated with the inoculated colloid. Since, therefore, radiation appears to interfere with the taking up of dye by the macrophages, inoculations of colloids should be given a few days before radiation, when these two kinds of treatment are combined. On the other hand, radiation causes a local accumulation of macrophages as soon as degeneration and necrosis begin. It might, therefore, be profitable to give colloid treatment about a fortnight after radiation under the assumption that the accumulated macrophages will bring much colloid to the tumour.

CONCLUSIONS.

(1) After radiation, macrophages do not take up trypan-blue so freely as normal macrophages. (2) About nine days after the radiation of tumours or of skin, at a time when degeneration changes set in, a local accumulation of macrophages occurs.

The radium used in this investigation was on loan from the Medical Research Council.

PRESENTATION HOSPITAL BEDS.—Lord Knutsford recently unveiled a commemorative tablet in Mellish ward at the London Hospital over a bed which is being endowed at a cost of 1000 guineas by the Paramount Philanthropic Society. This Society, which was founded in North London only two years ago, has already collected nearly £3500, chiefly from Jewish sources, and distributed it among 85 hospitals and kindred institutions in the Greater London area.—To celebrate its twenty-first birthday, the Nottinghamshire and District Bowling Association has endowed a cot, at a cost of £1000, in Nottingham General Hospital.

PUBLIC ASSISTANCE COMMITTEE AND RADIUM.—The Brighton public assistance committee have decided to purchase a quantity of radium at a cost of £1752. Mr. H. J. McCurrich, medical officer of the Brighton Infirmary, had reported to a subcommittee the need of the purchase, the more so as he found himself very much hampered by the system of hiring. The subcommittee agreed to the suggestion; also to obtain a loan for ten years to cover the cost. It was stated that the interest and sinking fund charges would amount to £237 per annum, and that the cost of hiring radium during the past 12 months was £134.

CLINICAL AND LABORATORY NOTES

MASTOIDITIS AS A COMPLICATION OF DIPHTHERIA.

BY E. ASHWORTH UNDERWOOD, B.Sc., M.B. GLASG., D.P.H.,

DEPUTY MEDICAL OFFICER OF HEALTH, COUNTY BOROUGH OF ROTHERHAM.

DIPHTHERIA presents a marked contrast to scarlet fever in that in the former disease ear conditions as complications are uncommon and mastoiditis is now very rare. Rolleston[1] does not mention the latter condition as a complication of primary faucial diphtheria; nor is there any reference to it in the works of C. B. Ker,[2] of Allbutt and Rolleston,[3] or of Nothnagel.[4] Schamberg and Kolmer[5] state that otitis media is sometimes a complication, but they do not mention mastoiditis. In these circumstances the case here reported may be of interest.

Bane,[6] in his paper published in 1917, stated that "the literature of diphtheria of the ear is not voluminous." One of the earlier references to the condition was by Billington in 1889. In 1901 Lewin[7] published a long paper dealing with an investigation of 60 cases of diphtheria and of diphtheria with co-existent scarlatina. From his discussion of the literature it is evident that the majority of the cases reported up to that date were really cases of scarlet-diphtheria and not of genuine diphtheria. He showed from his examination of pathological material that diphtheritic affection of the ear was fairly common in an anatomical sense, though clinically the condition was often not recognisable. Lewin concluded that diphtheritic otitis was usually due to a blood-spread of the virus and not to a direct spread from the throat via the Eustachian tube. There is no reference to mastoid disease in Lewin's paper, though he does mention a case of leptomeningitis.

In 1907 Kerrison[8] reported the case of a female patient (aged 19 years) who was suffering from genuine diphtheria. Otitis developed on the sixth day, and on the twelfth day acute mastoiditis was unmistakable. At operation the vertical limb of the sigmoid sinus was exposed and sinus thrombosis followed. Part of the jugular vein had to be excised before the condition cleared. In 1911 Barnhill and Wales[9] divided the otitis media caused by the Klebs-Löffler bacillus into three classes—viz. (*a*) primary diphtheritic inflammation; (*b*) otitis arising by extension from the nasopharynx; (*c*) secondary middle-ear infection accompanying diphtheria of the throat—the most common form. In 1926 Gowen[10] investigated the incidence of otitis in 15,000 infectious cases at the Philadelphia Hospital for Contagious Diseases. He found that otitis occurred in diphtheria only when this disease was co-existent with scarlet fever and measles; the incidence of otitis was then 50 per cent. and of mastoiditis 12 per cent.

The literature all points to the conclusion that, while in an anatomical sense diphtheritic affection of the middle ear may be fairly common, a clinically recognisable acute otitis is infrequent. Further, this form of otitis very rarely spreads to the mastoid cells.

RECORD OF A CASE.

The patient (aged 12 years) was a high-school boy of excellent general physique. He was admitted to hospital suffering from diphtheria, and from the history he appeared to be in the sixth day of the illness. On the day of admission the throat swab was positive, showing organisms which were morphologically diphtheria bacilli.

When he was seen on admission he was desperately ill. The face was pale and the cheeks showed a pinkish flush. There was "bull-neck" enlargement of the cervical glands on both sides, and this appeared to be the cause of considerable dyspnœa; no rib recession was noticed, nor were there laryngeal symptoms throughout the course of the illness. The parotid glands were normal. Blood had dried on the lips, and there was a slight exudation of blood from the gums. Slight rhinorrhœa was present, and the nostrils were somewhat excoriated. Fœtor was marked. A dirty, foul-smelling membrane covered the whole of the left side of the fauces and soft palate and extended forward on to the hard palate. Membrane was also present on the right tonsil and on the pillars. The membrane was greyish in colour with black patches, and separation caused considerable bleeding. Œdema of the soft parts resulted in the uvula being pushed down into the throat. The heart was normal in size. The sounds were regular and pure, but soft. Apart from slight roughness of the respiratory murmur, the lungs showed nothing of note. The liver and spleen were not enlarged or tender, but there was some slight tenderness in the right iliac fossa. The abdominal reflexes and the knee-jerks were present, but not active, and the pupils were equal and reacted to light. There was no sign of any paralysis.

On admission the temperature was 100·4° F., the pulse-rate 120, the respiration-rate 24. The patient had received 6000 units of antidiphtheritic serum before coming to hospital. On admission, 30,000 units were given immediately by the intramuscular route.

On the day following admission (seventh day of illness) the temperature had fallen to 99·2° F., the pulse-rate was 104–120, and the respiration-rate 22–26. The membrane, though still very adherent to the fauces and tonsils, was now separating slightly from the soft palate. There was still marked fœtor, but the faucial œdema had subsided slightly. The patient now showed profuse, thick, sanguineous nasal discharge. The enlargement of the cervical glands was slightly less than on the previous day. There was no increase in the area of cardiac dullness and the heart sounds were regular, though rapid and somewhat soft. Palpation showed slight increase of resistance in the right iliac fossa, but the abdomen was otherwise normal. Examination of the lungs still revealed generalised roughness of the respiratory murmur. During the course of this day the patient again received 30,000 units of antidiphtheritic serum.

On the following day (eighth of the illness) there was a slight improvement in the general condition, and 24,000 units of serum were injected intramuscularly. On the ninth day of the disease the patient showed a very definite improvement. The colour of the face had improved and rhinorrhœa was now absent. The throat was cleansing rapidly, and the faucial œdema had disappeared. The heart sounds were rather soft, but there was no evidence of cardiac dilatation. The temperature was now 98° F., the pulse-rate varied between 104 and 120, and the respiration-rate between 16 and 20.

The progress was uninterrupted until the twenty-seventh day of the disease, when the patient vomited in the evening. On the following day there was a slight but definite enlargement of the liver, and the lower border of this organ was tender. The area of superficial cardiac dullness was normal. The heart sounds showed extra-systoles, but the tone was quite good. There was no epigastric pulsation. The pulse-rate varied from 108 to 120. On the twenty-ninth day epigastric pulsation was present, and the area of superficial cardiac dullness was enlarged to the right. Right otorrhœa developed on the thirty-fifth day. The discharge became rapidly purulent, but there was no tenderness or œdema over the mastoid process. On the thirty-eighth day palatal paralysis was noticed. This complication was very persistent and fairly marked. By the sixty-seventh day of the illness the patient's general condition had improved considerably and the heart sounds were normal. There had been no ocular or pharyngeal paralysis, and the palatal paralysis was then only slightly marked. The purulent otorrhœa still persisted, however, in spite of treatment. During this period there had been no elevation of temperature and there was at no time any œdema over the mastoid process. On the seventy-third day the temperature rose to 100·4°, and on the following day the patient had pain in the ear and a suspicion of œdema over the mastoid. The ear discharge remained copious and purulent.

During the next week the temperature oscillated between 98° and 101°. There was slight tenderness over the mastoid region, and the œdema became more marked but was never very pronounced. There appeared to be a possibility that the condition would resolve without operative interference, and surgical advice upheld this view. Thereafter the temperature remained only slightly elevated (about 99°) until the eighty-seventh day, when it began to rise. The œdema and tenderness over the mastoid persisted but were never very marked. During this period swabs from the throat and from the right ear were negative for diphtheroid organisms. It became rapidly evident that the condition would not resolve without surgical interference. On the ninety-second day of the illness the patient was transferred to the Rotherham General Hospital, where the incomplete mastoid operation was performed by Dr. W. S. Wildman. At the operation considerable erosion of bone was found. Recovery was uninterrupted.

The patient was examined recently and was found to be in very good health. There was no evidence that he had ever had palatal or cardiac paralysis; the hearing was excellent, and showed no diminution on the side previously affected.

COMMENTARY.

The case is interesting in that the patient recovered completely, although he was extremely ill when he was admitted on the sixth day of the disease. During his illness he showed two types of diphtheritic paralysis, in addition to the otitis media and the rare mastoid complication. There was no evidence that an intercurrent disease—such as scarlet fever—was present and had caused the mastoiditis.

The insidious course of the ear condition is to be noted. The otorrhœa had persisted for 59 days and the mastoiditis for 19 days before the case came to operation. During this period the patient was not as ill as might have been expected. This slow but persistent progress of the pathological process in the mastoid antrum may be compared with the similar condition following scarlatina, in which the development is usually more acute. The mastoiditis appears to have been a true complication of faucial diphtheria, although definite proof of the interrelation was not forthcoming.

THE SULPHUR TREATMENT OF DEMENTIA PRÆCOX.

By P. C. Collingwood Fenwick, L.M.S.S.A.,
ASSISTANT MEDICAL OFFICER, EAST SUSSEX MENTAL HOSPITAL, HELLINGLY.

During a course of research work at the East Sussex County Mental Hospital and the London County Council Mental Hospital, West Park, Epsom, I have treated 30 cases of schizophrenia with sulfosin, a preparation of sulphur in olive oil, as described by Knud Schroeder.[1] All the cases I have treated have been males, and their ages have varied from 13 to 33. Some were recent admissions to hospital, others had been in for several years and had shown no improvement. They were of all types and conditions—stuporous, katatonic, grossly demented, and impulsive. The treatment has been carried out over a period of a year, and so far those cases that have shown improvement have not relapsed. The following table shows the results at a glance:—

Number treated	30	In statu quo	12
Discharged as cured	8	Still under treatment	3
Greatly improved	7		

Of those that were discharged from hospital, four had been in for over two years without showing any improvement, while the others were more recent admissions. Those classified as greatly improved were men who became clean in their habits and were able to show some keenness in the work of the hospital, and who before treatment had lived the lives of vegetables. Their discharge in the future is possible.

Technique and Dosage.—It has been my practice to use a 1 per cent. solution of sulphur in sterile olive oil, and to start the course of treatment by giving 1 c.cm. into the muscles on the outer side of the thigh and to increase the dose by 1 c.cm. until the patient has had 12 injections. As the temperature usually starts to rise about 12 hours after the injection, it is advisable to give the treatment at about 6 o'clock in the evening, so that the night's sleep is not interfered with by constant temperature recording, which is done every half-hour until the maximum is reached, and then every four hours. The fever is generally at its height about 18 hours from the time of the injection and may rise to 105° F., with or without rigors. In 48 hours it has usually returned to normal. Two injections are given each week, so that a full course takes six weeks, during which time the patient is kept in bed but is encouraged to occupy himself, which I think is an all-important factor. In the large number of injections that have been given in these hospitals not one case has shown the slightest inflammatory local reaction; the only complaint heard is of stiffness in the muscles into which the sulphur has been injected, but this passes off in a few days' time. It is advisable to warm the oil before using it, as it will then flow through the needle more easily. A three-inch needle is the most convenient to use.

In a few cases I have given a second course of 12 injections after an interval of about two months, but in no case has any further improvement been shown in the mental state.

Reaction.—When the temperature begins to rise the patient usually starts to sweat, loses his appetite, and in a few cases has become delirious, but these symptoms have never given rise to any real anxiety. In all cases there is a marked leucocytosis, and in one patient the white blood count rose to 73,600 at the height of his fever. The extent of the leucocytosis appears to give no indication of the ultimate prognosis. The liver does not seem to be affected by the sulphur, as there have been no cases of jaundice, and in every patient the van den Bergh reaction has been negative. The mental reaction has varied. One or two patients have definitely stated during their course of treatment that they thought the injections were doing them good and have asked for further treatment; others have lain like logs during the whole of the six weeks, whilst others have passed gradually from a world of phantasy to a world of reality but have needed constant guidance in their new world. It is of great importance to attempt to re-educate these schizophrenics on the days that their temperatures are normal during their course of treatment, and I think the good results obtained have in no small way been due to the interest and trouble that has been taken by the nursing staff.

One patient ran a temperature up to 102° F. for

(Continued at foot of next page.)

MEDICAL SOCIETIES

MEDICO-LEGAL SOCIETY.

AT a meeting of this Society on Jan. 22nd Sir WILLIAM WILLCOX took the chair, and Dr. NATHAN RAW read a paper on

The Coroner's Verdict in Cases of Suicide.

The word "suicide" had, he said, first been used in 1736 by Hales, author of "Pleas and the Crown." In English it was almost always used in a criminal sense, and in law felo-de-se and suicide were one and the same thing, although an attempt to commit suicide was not an attempt to commit murder but a common-law misdemeanour which could be tried at the quarter sessions. Under certain social codes and in certain circumstances suicide had been honoured, but in Anglo-Saxon times it had been regarded as a crime against God and the church; a verdict of felo-de-se had meant that the suicide's goods and lands would be forfeited, the widow would lose her dower, and the body would be buried in some public highway with a stake through it. Now that these penalties had been modified, Dr. Nathan Raw argued, the word "suicide" should be expunged and the verdict should be "did feloniously kill himself," except on those rare occasions when there was sufficient evidence for the jury to add "not being of sound mind." The phrase "committed suicide whilst temporarily insane" was a contradiction in terms, for "to commit" in this sense meant "to be guilty" of a crime, which was impossible for an insane person. The suicide-rate in England was 9 per 100,000, but the number was steadily increasing, though there was a great decrease in the number admitted to prison for attempted suicide.

Mr. LLEWELLYN JONES said that if coroners kept to the letter of the law they would have in most cases to direct the jury to return a verdict of felo-de-se. One of the most useful of enactments was that which allowed a coroner to conduct an inquest without a jury. The coroner should sympathise with the friends and relatives and avoid returning a verdict which would cast a stigma on the family. The verdict of felo-de-se could have no deterrent effect. Publicity, especially for letters found on the deceased and the manner in which the act was committed, was most undesirable, for it victimised defenceless persons and induced unstable individuals to imitate the suicide. Attempted suicide had decreased, but successful suicides had increased, relatively and absolutely. Much could be done to reduce suicides by enforcing the restrictions on the sale of dangerous drugs.

Dr. MORGAN FINUCANE maintained that most suicides were due to melancholia and allied states, usually characterised by delusions. In disagreement with Dr. Raw, he preferred the verdict of "unsound mind," which, though perhaps not legally correct, was humane. He advocated in cases of attempted suicide a verdict of "guilty but insane," and the detention of the prisoner for treatment, for many melancholic patients repeated the attempt.

Dr. E. F. HOARE, coroner for the Lewes district of East Sussex, cited the case of a governess who had committed suicide because her fiancé could not afford to marry her. He thought that the man had acted reasonably and sensibly and that the girl's mind had become unbalanced. He had, he said, directed the press to withhold the name of the man, who had actually not heard of the suicide. When compelled to read letters, he restricted himself to extracts which threw light on the mental attitude of the deceased. Coroners were hampered in returning a verdict of felo-de-se by the uncertain attitude of some insurance companies; juries were apprehensive lest they should deprive the widow of her benefit. He doubted whether a coroner sitting without a jury could return a verdict of felo-de-se. Juries were apt to return the verdict of "unsound mind" in cases where the coroner might almost consider the act reasonable—as in the suicide of a victim of rodent ulcer—and to return felo-de-se in cases where the medical eye saw unmistakable signs of mental illness. He had great hope that the Mental Treatment Act would reduce the number of suicides by facilitating early treatment.

TRUTH THE BEST GUIDE.

Dr. LETITIA FAIRFIELD said that in the old days when a family would sooner be branded with a crime or insanity than with a sin, the "unsound mind" verdict might have been preferable, but that nowadays families dreaded the stigma of transmissible illness. She had known cases in which a verdict of "suicide while of unsound mind" passed an unjustifiable and deleterious slur upon the hereditary mentality of a family, and in which children had grown up overshadowed by the fear of insanity although the suicide of the parent might have had, to a humane observer, a reasonable motive. Truth was probably the best guide in this matter. She considered that the coroner ought to say more about the mental state of a deceased who had exhibited undoubted text-book symptoms of insanity which had been ignored by the friends and relatives; for instance, when the deceased had been placed in a nursing home under wholly inadequate care instead of being given mental treatment. This was a definite evil which was responsible for many unnecessary deaths every year; she hoped that the Mental Treatment Act would abate it. The "suicide pact" was often associated with most pitiable circumstances and the survivor had often been punished sufficiently. Nevertheless, it was sometimes employed to rid the accused of an insoluble tangle, and the penalty could probably not be safely abolished altogether.

Dr. DORIS ODLUM regretted that the law had taken such a Draconian point of view. It imposed penalties upon the body of the offender after his death in much the same way as a child punished its toy for being

---

(*Continued from previous page.*)

some four weeks after he had finished his course. Mentally he showed marked improvement, and no physical signs could be discovered. He complained of nothing, and so a war-time diagnosis of P.U.O (pyrexia of unknown origin) had to be attached to his case-sheet.

Although it is recognised that cases of dementia præcox have periods of remission, during which they are well enough to return home, I think it is justifiable to try the sulphur treatment on all new cases, for no harm is likely to occur and in many cases progressive dementia may be prevented or at least hindered.

I am indebted to Dr. F. R. P. Taylor and Dr. Norcliffe Roberts, the medical superintendents of the hospitals mentioned, for kind permission to record the results of my investigations, and to Dr. Geoffrey Shera, pathologist to the East Sussex Hospital, for his help in performing the various laboratory tests.

broken. The only other explanation was that the penalties were meant to be deterrent, but no evidence existed that purely retributive measures ever deterred anybody. The State had therefore reached an impasse where the public were taking the view that a man had more or less of a right to kill himself if he wished to, and that it was wicked to visit his act upon his unfortunate relatives. Coroners' juries were therefore placed in the position of having to say what they really did not believe. Persons who attempted suicide were nearly always victims of profound emotional imbalance, though they were not always deluded, and it was reasonable to suppose that this generalisation applied also to persons who succeeded. Survivors should be treated, not punished. Fortunately, the Home Office directed the police to proceed very leniently in cases of attempted suicide, and a charge was not often made if it was possible to place the survivor under care. It was necessary to revise drastically and publicly the ideas underlying the legal attitude to suicide.

Dr. **Bentley Purchase** agreed that "suicide while of unsound mind" was a contradiction in terms, and stated that neither he nor Sir Walter Schroeder ever used the term "suicide" officially. It was not used on the official forms. A coroner sitting alone could not return a verdict of felo-de-se and was therefore inclined to seize upon evidence of earlier mental trouble.

Dr. **Knyvett Gordon** suggested that gas companies should make their gas too obnoxious to be used as a means of self-destruction.

Mr. W. F. **Chadwick** pleaded for the institution of a verdict of "justifiable homicide."

Mr. C. G. **Moran** pointed out that insanity and unsoundness of mind were not the same thing. There was a legal definition of insanity and there might, for all he knew, be a medical one, but he had never yet known anybody to be of perfectly sound mind. The question was primarily one of policy, and a verdict of unsoundness of mind truthfully covered such states as emotional imbalance, hopelessness, and worry.

Dr. **Temple Gray** suggested the verdict "did kill himself when suffering from mental illness," which would include all but felonious suicide.

The **Chairman** deplored the ease with which educated persons could still obtain drugs of the barbituric acid group. The prevention of suicide was a matter for the psychiatrists, who should educate the public.

Dr. **Nathan Raw** replied.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ODONTOLOGY.

At a meeting of this Section held on Jan. 26th the chair was taken by Mr. **Carl Schelling**, the President. Dr. A. A. **Osman** read a paper on the

Importance of Sugar in the Diet of the School-child.

The amount of sugar required by children of school age, had, he said, long been a matter of dispute. There was an almost universal craving among children for sweet things, suggesting an underlying physiological need, but there seemed to be some evidence of ill-effects from excessive consumption. The most important possible danger was damage to the teeth, and most of the objection to sweets had come from the dentists. Dr. Osman thought that the pendulum had been allowed to swing too far and that not a few children were suffering from relative sugar starvation. The young child was ceaselessly active during waking hours. Every little thing it did was done with its whole body and mind, and the output of energy was enormously greater than that of an adult. Clearly, then, an adequate supply of readily assimilable and easily combustible fuel was of great importance. The primary fuel of muscle was carbohydrate, and immediate needs were best met by the simpler types, the mono- and di-saccharides; the more complex poly-saccharides were used to replenish stores at leisure. Did not the child's craving for sweets arise from this very fact?

The symptoms of sugar deprivation could be divided into major and minor; the major symptoms were "bilious attacks" or "cyclical vomiting," which occurred between the ages of 4 and 13 and consisted of attacks of sickness with headache, fever, anorexia, and muscular prostration. There was usually constipation, sometimes succeeded by diarrhœa. There were three common causes: mental excitement, infection, and physical exhaustion, all factors making a rapid demand upon sugar reserves. A low blood-sugar was not the rule; rather the blood-sugar was maintained at a normal level at all hazards, only falling when the glycogen reserve of the liver was used up. Most bilious attacks were of this nature, and over 30 per cent. of children suffered from them. The minor symptoms of sugar shortage could be summed up in the word "fatigue." The child looked physically and mentally exhausted, pale, languid, depressed, with dark rings under the eyes, expressionless face, and listless stance. Such children were usually brought to the doctor for anæmia, headaches, flabbiness, fainting, constipation, "growing pains," or asthma. In many the symptoms had been aggravated by the provision of extra milk. Many had parted with their tonsils and not a few with their appendices, and artificial sunlight had been prescribed indiscriminately. All these symptoms cleared up when the sugar allowance was increased, and the gain in health and spirits was enormous.

A considerable proportion of the hospital class seemed to be suffering from some degree of acidosis, and apparently the importance of ketosis as a cause of symptoms in childhood had been unduly exaggerated. Certainly, neither ketosis nor hypoglycæmia was the constant biochemical abnormality in the subnormal child; acidosis was the condition found, and it disappeared when the sugar in the diet was increased.

No rules could be laid down for the amount of sugar required; it depended on the individual child. General directions to cut down fat and increase carbohydrate did not usually suffice; sugar must be supplied actively. Glucose had the advantage that it could be given as a medicine. The following prescription had been found successful in preventing attacks of cyclical vomiting in highly strung children: at all meals three to four teaspoonfuls of sugar per cup of weak tea or small glass of lemonade, a sandwich of bread and butter thickly spread with Demarara sugar and a similar sandwich at bed time; plenty of syrup, honey, and jam and fresh fruit; limited fat and milk; powered glucose in lemonade between meals, or boiled sweets, toffee, and candy without stint. Except diabetes, and possibly some cases of diarrhœa, Dr. Osman knew of no illness in childhood made worse by the addition of sugar to the diet, and was convinced that an enormous amount of chronic misery and ill-health could be prevented if we were more willing to learn from the child than to teach him.

DISCUSSION.

Mr. F. W. BRODERICK agreed that an increase of sugar did not cause caries but cured it and improved the child out of all knowledge. He inquired whether Dr. Osman gave alkalis, and, if so, whether he gave them on an empty stomach so as not to upset the acidity of the gastric juice and prevent calcium absorption. He also asked how Dr. Osman treated the spots which came out as the result of sugar feeding.

Mr. W. L. BULLEID said that the idea that sugar could be held in solution against the teeth would not survive a moment's thought. He had habitually prescribed boiled sweets and glucose, which never did any harm and reduced susceptibility to caries, which was endogenous. Sugar was sometimes a wonderful prophylactic for the type of child whose nervous reactions made him a pest before, during, and after a party. Dental surgeons made the mistake of not differentiating sufficiently clearly between pure, soluble sugar and sticky sweets such as toffee and chocolate, which contained fat and adhered to the teeth. Boarding-schools were often to blame for sugar shortage in their dietary and for their restrictive regulations. Adults who suffered from travel sickness often benefited from doses of barley sugar.

Mr. G. T. HANKEY inquired whether there was any relation between calcium deficiency and sugar deficiency.

Dr. KINGSTON BARTON declared himself wholly on the side of the dental surgeons; he thought the mouths and stomachs of our children were being demoralised by sweets. The beet sugar which was so much used nowadays was much more deleterious than cane sugar. Sugar should be given in the form of food, but there should be an absolute taboo against sweets eaten promiscuously. The French knew the value of eau sucrée against thirst and fatigue, and explorers in all climates relied largely on sugar. Glucose was not a good form in which to give sugar, because it was likely to be impure. White sugar tended to constipate and brown sugar to relax, and a balance should be struck between the two.

Dr. R. P. GARROW doubted whether beet sugar was inferior to cane sugar. He inquired what Dr. Osman meant by extra milk and underfed children. The children who drank extra milk in the morning under the scheme of the National Milk Publicity Council benefited very greatly. No one could say what constituted a balanced diet, but milk was said to have a balancing effect.

Mr. A. T. PITTS said that the dental surgeon should adapt his views on dietetics to the general nutritional requirements of the child, but that dietitians should take account of some of the prevailing views on oral hygiene. He inquired whether Dr. Osman disagreed with the work of Dr. Corry Mann on children fed with milk. It was better to prescribe glucose than to allow the child to help himself to boiled sweets when he wanted to. He doubted the wisdom of giving children sweet sandwiches just before sending them to bed.

Mr. R. E. RIX inquired whether glucose ever produced epileptiform attacks in children with no previous history of fits.

Dr. E. W. FISH maintained that caries was an hereditary condition; it always occurred on the contact points of the teeth in permeable faults of the enamel, and not in spots which might have been affected by vitamin deficiency. Although accelerated by fermentable carbohydrates, it would occur in any event.

Mr. J. G. TURNER suggested that the real cause of much caries might lie in focal sepsis, especially of the nasal sinuses. Disease of the intestinal tract might produce an excess of carbohydrate in the diet by interfering with the digestion.

Mr. D. M. SHAW said that in children who normally did not get enough carbohydrate an addition of sugar to the diet was definitely beneficial.

The PRESIDENT remarked that certain races who ate no sugar had good teeth, but that Irish peasants developed bad caries on butter-milk and oatmeal. He had chewed sugar-cane as a child in Cuba, but had had no caries until his twentieth year.

Dr. OSMAN replied that alkalis had produced no results in acidosis, and that spots went away again if more sugar was given. Some children could not deal with an extra glass of milk in the morning unless it was balanced by a corresponding amount of sugar. He suspected that asthma and bilious attacks had increased in Dr. Corry Mann's children. Skimmed milk was as beneficial as whole milk. Fits caused by sugar must be very rare. Nasal sinusitis was not often seen in the out-patient department.

CASUAL COMMUNICATIONS.

Mr. J. E. CURNOCK described and illustrated by slides a cyst of the mandible which had occurred in a man who had been edentulous for 14 years before any clinical signs had appeared, and which was therefore probably not odontogenic; it might possibly have arisen from the ramus of the first branchial arch.

Mr. HANKEY described an unsuccessful attempt at replantation of two central incisors in a schoolboy. The teeth had been recovered immediately and placed in a solution of thymol for a few minutes before replantation, but in spite of the careful coöperation of the patient, and although X rays had shown no change for four months, osteoclasia had eventually set in.

Mr. TURNER said that he had succeeded in replanting teeth even after boiling them.

Mr. H. A. KENSHOLL suggested that infection had existed from the beginning but had not produced sufficient decalcification to show on an X ray film.

Mr. G. C. FRIEND inquired the most suitable solution to use in such cases.

Mr. HANKEY replied that sepsis had probably existed, but must have been very low grade. The solution used must not be too strong. Thymol was the correct drug to use, but the effervescent thymol tablets had probably been too weak.

SECTION OF MEDICINE.

AT a meeting of this Section on Jan. 27th Dr. R. A. YOUNG, the President, took the chair, and a paper on the prognosis and treatment of

Heart Disease Complicating Pregnancy

was read by Dr. CRIGHTON BRAMWELL (Manchester). In opening Dr. Bramwell remarked that the information on this subject in most current text-books was neither adequate nor up to date. One reason for this was that the obstetrician could hardly be expected to keep in touch with all the recent advances in cardiology, while the cardiologist, on the other hand, did not often have a chance of making a satisfactory study of these cases. He was often asked advice about treatment, or to give a prognosis, but he did not have the opportunity of supervising this treatment; often he did not hear whether his prognosis was correct, and there was nothing so disastrous to progress as ignorance of one's mistakes.

The important question was whether, in the face of heart disease, the pregnancy should be allowed to run its course. (1) What was the immediate additional risk due to heart disease? (2) Would pregnancy and labour impair the woman's future health, by causing a permanent aggravation of the cardiac disability? If it were decided that the pregnancy should be terminated, how and when should that be done? During the last three years, at St. Mary's Hospital, Manchester, Dr. Norah Regan and he had been watching cases of heart disease through their later weeks of pregnancy, their labour, and the ensuing puerperium, and had been examining them at intervals afterwards to see whether the heart showed evidence of further damage consequent on the pregnancy. This paper was based mainly on 82 unselected cases showing all grades of heart disease—i.e., every patient attending the hospital during 18 months was examined for heart disease, and 79 were the result of examining over 3000 women at the antenatal clinic with three admitted as emergencies who had not been to that clinic. Being unselected this series approached the scientist's idea of a "clean experiment." Each woman was questioned as to any troubles in the present or previous pregnancies, especially as to congestive heart failure, with engorgement of the veins in the neck, enlargement of the liver and œdema of the feet, and cardiac enlargement. A six-foot X ray film of the case was studied, also the rhythm recorded. The patient was then brought at intervals of 14 days for examination during the remainder of the pregnancy. Particulars of her progress through labour, and any signs of cardiac distress were recorded by the obstetric officer in charge of the case and the speaker or his colleague saw the patient in St. Mary's Hospital at some time during the puerperium. The woman was asked to come for re-examination a month after the confinement, and thereafter every three months. Those who did not so report were visited in their homes. Owing to changes of address, he had lost sight of 12 of the 82 cases.

Ætiology.—In the 82 cases the ætiology was as follows: rheumatic fever, 20; chorea, 17; rheumatic fever and chorea, 10; patients who had had "rheumatism," 11; tonsillitis and growing pains, 11; mitral stenosis but no rheumatic history, 9; congenital lesions, 3; congenital heart disease in which there were no heart murmurs, 1. The severest cases were those who had had symptoms of heart disease prior to the onset of the pregnancy. Eleven of the women had bronchitis (in four it was of recent origin, seven of old standing). In three the bronchitis was an aggravating factor in the patient's cardiac condition. Strange to say, only 5 of the 82 cases had hæmoptysis. Two of these who had aortic incompetence in addition to mitral stenosis had been in poor health ever since the confinement. Hay and Hunt had a series of cases which showed 30 per cent. of hæmoptysis during pregnancy. Mitral stenosis was found in 67 cases, this being accompanied in 7 by aortic incompetence. Mitral incompetence was diagnosed in 10 cases in which there was a definite rheumatic history and a loud systolic murmur in the region of cardiac impulse. One of these women subsequently developed renal toxæmia and so was delivered prematurely at the thirty-second week. None of the fatal cases had aortic incompetence. In six cases there was definite evidence of a fully developed congestive heart failure; three were admitted as urgent heart failure cases who had not been to the antenatal clinic. Two of these last-named six patients died, three had been in poor health since their confinement, their condition having been aggravated by the pregnancy, while only one of the six had done well. In five of the six cases the heart failure was not accompanied by auricular fibrillation; they were cases of failure with normal rhythm, contrary, therefore, to what was usually found in cases of rheumatic heart disease. Six patients gave a history of having suffered from œdema as well as dyspnœa prior to pregnancy, and they were expected to develop congestive heart failure during the pregnancy in which he and his colleague observed them. That proved true, however, in only two of the cases. It was difficult to account for the fact that in six patients who had heart failure when seen only two gave a history of having had it prior to the pregnancy, whereas of six with a positive history two only developed heart failure. There were two possible explanations: (1) that the œdema of the feet of which the patients spoke might not have been of cardiac causation; (2) that the patients were not closely cross-questioned, and they might have forgotten that they had had œdema, hence the heart failure might really have been the second attack.

Fibrillation was the most grave of the cardiac disorders associated with pregnancy; Leyland Robinson, of Liverpool, published 18 cases of fibrillation, of whom 13 died, but 8 of the 13 had signs of congestive heart failure and were not under antenatal supervision, nor did they receive hospital treatment during their pregnancy. Hay and Hunt had four cases of fibrillation in their series with one death. Forty-three of the cases were delivered at full term, 25 prematurely (eight of them prior to the thirty-seventh week), induction was carried out in 12, and in two Cæsarean section was done.

Fatal cases.—Of five cases which died the first was a primipara aged 28, who was admitted to hospital because of hæmoptysis, and had a pulmonary embolism three days after her confinement; she had had dyspnœa and hæmoptysis prior to the confinement, and low blood pressure—namely, 100 systolic. The second was admitted as an urgent case because of heart failure. She developed fibrillation at the thirtieth week, and died from septic complications. The third was also admitted as an urgency with heart failure, and was delivered the day following admission, in her thirty-second week. She had had frequent attacks of acute pulmonary œdema both prior to and after confinement, and died from it six weeks after confinement. The fourth case was a primipara aged 21, who had heart-block, and died apparently of failure of the peripheral circulation, immediately after labour. The last case was that of a woman who had already borne 13 children, and she declined to carry out instructions and suggestions; she, indeed, seemed to have no wish to live.

Of the 66 cases of the series with whom contact had been maintained, and who were seen at intervals of from three months to two years, 27 had been free from symptoms since pregnancy, 36 stated that though they had now dyspnœa on exertion, it was no worse than prior to the pregnancy; in three the cardiac condition had clearly been aggravated by the pregnancy.

Deductions.—When definite œdema, enlargement of liver, moist sounds at the base of the lungs were present, one must expect trouble in the pregnancy; the same was true of patients with auricular fibrillation. Trouble was looked for in 13 of the 82 cases, but it was actually encountered in only eight. Five of those died, in three the heart trouble was aggravated. On the whole, it could be said, as a result of the study, that the prognosis of heart disease complicating pregnancy was less gloomy than it was often held to be. Another feature was that the valvular lesions in this series had afforded no prognostic help; it seemed immaterial whether one was dealing with mitral regurgitation, stenosis, or aortic incompetence—i.e., as to whether the prognosis was good or bad in those cases. Most writers had laid grave stress on cardiac enlargement, and in his experience people who had large hearts did worse than did those whose hearts were not enlarged; several of his cases with cardiac enlargement, however, did well, though, on the other hand, three with enlargement were among the fatal cases. One could not, in dealing with prognosis, leave out of consideration extraneous circumstances; the woman in good circumstances would have little additional work thrown on her because of the child, but it was far otherwise with the poor.

Treatment.—The physician should, Dr. Bramwell thought, forbid pregnancy in cases in which there had been definite proved congestive heart failure in the past; also in the case of patients who had auricular fibrillation. Apart from the heart failure, there was a danger that they might get a cerebral or a pulmonary embolus. If the cases were not seen in time to warn against pregnancy, if seen early in the pregnancy the uterus should be emptied; or later still, Cæsarean section should be done. But emphatically the first thing was to treat the heart failure, and irrespective of the pregnancy. In less severe cases the patients should have prolonged rest and other precautions must be taken, then a labour could be successfully negotiated which might otherwise have been fatal.

DISCUSSION.

Dr. L. J. WITTS spoke of the frequency with which women with congestive heart failure died in labour of septic complications. He had even heard of women in labour with this heart trouble unexpectedly dying of tetanus, and he wondered whether Cæsarean section was advantageous on that account also.

Dr. C. MOIR also wondered whether, for these heart cases, spinal anæsthesia was best; in his own experience of such cases it had proved satisfactory. Many obstetricians said there was real danger if the child was born before the placenta was delivered, the idea probably being the sudden diversion of a large volume of blood from the uterine into the general circulation, so that there was a liability to sudden death at that stage. Therefore, it was advised that on no account should delivery of the placenta be hurried, one or two hours being allowed if necessary before the placenta was expelled. In such difficulty should not venesection be done?

Dr. WILLIAM EVANS expressed his surprise at the low incidence of auricular fibrillation in this series of cases; John Parkinson's series gave a considerably higher incidence. Many authorities held that the heart did not enlarge in acute congestive failure; the fact that the apex-beat shifted upwards might be due to the enlargement of the liver.

Dr. OLIVE RENDEL said that in a series of 200 cases which she had studied, not more than four had auricular fibrillation. Most of her cases were those of mitral stenosis, with or without aortic reflux. In that series there were four deaths, none of them due, except one, to auricular fibrillation, and that one had also malignant endocarditis. Two of her cases went into fibrillation after delivery. She asked what was Dr. Bramwell's prognosis in cases of hæmoptysis; her own view was that even a small hæmoptysis, certainly when repeated, constituted an indication for the termination of the pregnancy.

The PRESIDENT said he had been impressed by the way in which cases of heart disease weathered pregnancy and delivery Recently, there was admitted to his ward after delivery, a woman who had signs of congestion, mitral stenosis, and cerebral embolism. She developed some fever, and eventually died. She was found to have unsuspected right-sided infective endocarditis.

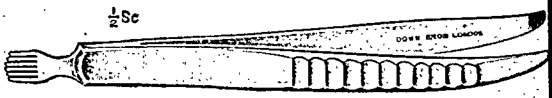
REPLY.

Dr. BRAMWELL said that Cæsarean section had the one great advantage that it could save the patient from the last month of her pregnancy, the worst time, and one could regulate the blood loss. With regard to anæsthetics, Mackenzie used to say there was nothing like chloroform for these cases, as he had no trouble with it, and the speaker thought there was still something in the advice. He would hesitate to agree to spinal anæsthesia in a case with a systolic pressure of only 100 or 105, but his practice was to leave the anæsthetic to the discretion of the administrator. He had not had experience of trouble due to quick delivery of the placenta. Fibrillation was liable to occur at any time in an old-standing case of mitral stenosis. When there was dyspnœa and heart failure seemed to be impending, the patient was brought into hospital for a period of rest and treatment, and with very satisfactory results.

NEW INVENTIONS

COMB DISSECTING FORCEPS.

THE comb dissecting forceps shown in the accompanying illustration has been made to my design. The comb end is rigid and the blades flexible. It embodies the principle of the well-known "Kelly's comb," and is most useful in performing the radical operation for cancer of the breast. After the fascia has been divided along the front of the axillary vein with a light touch of the scalpel, the forceps is held in the reverse position and the comb sweeps the axillary contents away from the posterior aspect of the vein commencing at the apex of the axilla. Branches of vessels and nerves are displayed at their origin and clamped or preserved as desired. The proximity of the comb to the handle enables this to be accomplished with ease and precision. I have found the forceps useful for similar types of blunt dissection elsewhere, especially for stripping fascial or omental structures away from vessels, pedicles, ducts, and the necks of hernial sacs. The blades meet at the point only. The instrument serves the double purpose of dissecting forceps and Kelly's comb, so that one instrument less need be taken to a breast operation.



It is made in stainless steel by Messrs. Down Bros., Ltd., St. Thomas's-street, S.E.

REVIEWS AND NOTICES OF BOOKS

Sir D'Arcy Power's Selected Writings, 1877–1930.

Oxford: Clarendon Press. 1931. Pp. 368. 25s.

THIS handsome volume is made up of 16 selected essays and addresses by Sir D'Arcy Power, and its publication has been arranged by a group of friends to mark the occasion of his seventy-fifth birthday, which occurred in November, 1930. For more than half a century Sir D'Arcy has used his pen to forward and foster medical knowledge along many lines, technical, clinical, historical, and biographical, and the bibliography appended to the book ranges in the matter of dates from 1887 until to-day, containing more than 600 headings. Such a mass of material has required close sifting in order to reduce it to a reasonable size, and, while no doubt much has thus been eliminated which well deserved reprinting, there remains a series which is compact of wisdom and information delightfully conveyed, and which justifies an important manner of permanent record. The bibliography testifies to the number of baskets in which Sir D'Arcy Power has put his eggs, but the articles selected for reprinting have appeared mainly in the *British Journal of Surgery*, the *Proceedings* of the Royal Society of Medicine, and the *St. Bartholomew's Hospital Gazette*. Two of the articles, forming public orations, have appeared in full in THE LANCET, while others will have had their origin in or sustenance from the author's frequent contributions to the *British Medical Journal* upon medical history. Again the many and short biographies from Sir D'Arcy's pen of members of the medical profession, whose careers have warranted inclusion in the Dictionary of National Biography, will have been drawn upon to supply the wealth of historical detail displayed, though none of them is here in extenso.

The selected essays include the Hunterian Oration, delivered before the Royal College of Surgeons of England in 1925; a brilliant account of Harvey as a traveller contributed to the Historical Section of the Royal Society of Medicine; a documented history of the first 100 years of the Royal College of Surgeons, which appeared in a short-lived medical weekly entitled *The Physician and Surgeon;* and an address on the early origins of surgery in the United States, in which the connexions between the American pioneers and the science of the mother country is set out. These four papers illustrate well the accurate knowledge upon which Sir D'Arcy has built up his literary constructions and the graceful style with which they are adorned. Again, no better method of ascertaining what the medical profession has stood for, while the last five centuries were going by, could be suggested than the reading of such a story as the Vicary Lecture, delivered at the Royal College of Surgeons of England. Here is described the education of a surgeon when Vicary, in virtue of age and position was foremost, as the author points out, amongst a band of pioneer surgeons in the reign of Henry VIII. who desired to see their calling advanced from a trade to a profession. In this essay will be found notes upon the system of apprenticeship which prevailed with the Barber Surgeons Company at the time and for a further 250 years, and a short reference by the author to the abuses which at the end of the eighteenth and beginning of the nineteenth century brought the system into abuse, shows what a powerful incentive it formed to the reforming energies of Wakley and his coöperators when founding THE LANCET.

Other chapters of interest to all who would follow the evolving history of medicine—a study whose importance is receiving to-day more attention—are that on the Diaries of the Rev. John Ward, once the treasured possession of the Medical Society of London; that on the condition of Pepys's eyesight which led him suddenly to discontinue his journal; a learned presidential address delivered before the Section of Comparative Medicine of the Royal Society of Medicine, in which, among many other things, will be found an interesting note on William Kitchen Parker; and two papers dealing with episodes in the history of St. Bartholomew's Hospital.

This is a good book, containing much learning put lightly.

Die Chirurgie.

Edited by Prof. M. KIRSCHNER (Tübingen) and O. NORDMANN (Berlin). 1930. Berlin and Vienna: Urban and Schwarzenberg. Vol. II., Fascs. 26 and 29. M.18 and M.16. Vol. III., Fasc. 27. M.14.

THE section of this great work which describes the surgery of bones is written by Dr. Leopold Schonbauer, of Vienna. The physiology and structure of bone is first considered and then what is called the biology under which heading is included such general changes as osteoporosis and osteosclerosis. The chief value of this part of the book is that it describes a great deal of work which has been done upon the general pathology of bone and gives full references. The account is rather bewildering, since the author does not give a critical survey of what is known at the present day of the different subjects; but all the same the student bent on mastering the subject would find it difficult to discover a better guide to his reading than is here presented. The rest of the book describes the various diseases of bone and also fractures. It reaches a high standard and deserves praise, but there are some omissions. For instance, W. Orr's treatment of septic compound fractures is not described, though it was published five years ago, and some of the latest work on the relation between the parathyroids and osteitis fibrosa is not very fully dealt with. Some extraordinary illustrations of patients complete a very fine collection of pictures of rare bone diseases.

In Fasc. 29 Dr. A. Winkelbauer (Vienna) describes operations upon bones and joints. He gives a straightforward account of operations on these structures, including many very rarely performed, at any rate in this country, such as the Wladimiroff-Mikulicz osteoplastic resection of the ankle; but we could find no descriptions of the commonly performed subastragaloid and midtarsal arthrodesis, or of cuneiform resection for inveterate talipes equino-varus. In removal of the internal semilunar cartilage of the knee the author sees no objection to severance of the internal lateral ligament. He apparently holds that complete excision of the meniscus is necessary, in this respect departing from the teaching of English surgeons, who have probably had more experience of this injury than anybody in the world. Bone grafting is not very thoroughly dealt with. The illustrations are as good as in the other sections of this system of surgery.

Vol. III., Fasc. 27, is devoted to a complete monograph on the surgery of the spinal cord and its membranes, by Dr. E. Heymann (Berlin). The work is extremely well conceived and carried out. Anatomy and physiology as the basis of neurological diagnosis are fully described in the first chapters and are followed by accounts of the various pathological conditions amenable to surgery. The neurological surgeon who seeks information on some points in the technique of diagnosis or operation, or desires to know the results of chordotomy or posterior root resection or other intervention will not be disappointed if he consults Dr. Heymann's book. Here again the illustrations are well selected and well drawn.

Tuberculous Intoxications.

By JOSEPH HOLLOS, M.D., Pathologist of St. Vincent's Hospital, Staten Island, New York. Edinburgh: E. and S. Livingstone. Pp. 132. 10*s.* 6*d.*

THIS book is an enlargement of the author's earlier book on "The Tuberculous Intoxications," published in Budapest in 1909. It is based upon the work of Carl Spengler on cellular immunity, the patients being treated with very weak dilutions of immunity substances extracted from the washed red blood corpuscles of immunised animals. The book has chapters devoted to symptoms of tuberculosis such as endocrine disturbances, neurasthenia, rheumatism, dysmenorrhœa and other menstrual disturbances, gastric and intestinal disturbances. We fear that clinicians are not likely to endorse a large number of the statements made therein; for example, "In the vast majority of cases rheumatic arthritis is nothing but one of the masked forms of concealed tuberculosis," and "The greatest part of menstrual disorders are of tuberculous origin, and they can be completely cured, or, at least, ameliorated through specific antituberculous treatment." A large series of cases is given which the author has treated with immune blood by Spengler's method.

Children of the Covered Wagon.

Report of the Commonwealth Fund Child Health Demonstration in Marion County, Oregon, 1925–1929. By ESTELLA FORD WARNER, M.D., and GEDDES SMITH. New York: Commonwealth Fund Division of Publications. 1930. Pp. 123. $1.

Cross-Sections of Rural Health Progress.

Report of the Commonwealth Fund Child Health Demonstration in Rutherford County, Tennessee, 1924–1928 (HARRY S. MUSTARD, M.D., Director, Rutherford County Demonstration). New York: Commonwealth Fund Division of Publications. 1930. Pp. 230.

IT is the policy of the Commonwealth Fund to inaugurate and conduct for a limited period in any district some service which appears to be needed there, with the object of demonstrating that need and how it can be met. In pursuance of this policy an intensive campaign for the betterment of health in Marion County, Oregon, U.S.A. was carried on during the years 1925 to 1929 inclusive. In a little book Dr. Warner and Mr. Geddes Smith describe the procedure adopted by the Fund, the staff and equipment required to carry out the scheme, its total cost, and the apparent effect of the efforts. The machinery set up was that which would be regarded in this country as the normal organisation of a progressive rural area, including medical staff, dentists, inspectors, nurses carrying out the duties of school nurses and health visitors, and the necessary clerical assistance. Special attention was devoted to the care of expectant mothers and young children, and an intensive and successful campaign was conducted in order to induce the public to accept immunisation against diphtheria. All this is described in popular language. The book is beautifully produced and contains a large number of admirable photographic illustrations. For the guidance of those who are specially interested in public health administration, tables showing the movement of various case-rates and death-rates in the county during the ten years, 1920 to 1929, are included in an appendix. These figures show that the mortality due to childbirth, the infant mortality (and notably the neonatal mortality), the mortality from most of the communicable diseases and the incidence of the latter have declined to a greater extent during the period than they have in the State of Oregon and in the United States registration area generally. The record of this work should be a stimulus to the health authorities of similar areas in America and throughout the world. That it has proved so locally is evidenced by the fact that the organisation is being officially carried on now that the work of the Commonwealth Fund is done.

The second book is also the result of a demonstration carried out in a rural area by the Commonwealth Fund. In this instance it was conducted for five years ending December, 1928, in Rutherford County, Tennessee. The same objects were aimed at as in Marion County, Oregon, and a similar procedure was adopted. The results appear to have been equally successful and the demonstration has had the effect not only of persuading the county health department to carry on the scheme out of public finances, but also of stimulating the public health programme of the whole State.

Therapeutic Uses of Infra-red Rays.

By ANNANDALE TROUP, *M.C.*, M.B., Ch.B. With foreword by Sir WILLIAM WILLCOX, K.C.I.E., C.B., C.M.G., M.D. London: The Actinic Press, Ltd. 1930. Pp. 57. 5*s.* 6*d.*

THIS small volume is not a text-book, but is a clear elementary exposition of infra-red therapy, written for his colleagues by a general practitioner. It will be found useful by those not acquainted with the principles of radiant heat therapy, who require an introduction and practical help in choosing apparatus. The treatment of the subject is elementary throughout and there are few references to the literature.

Dr. Troup has had some years' experience of infra-red therapy and is an enthusiastic believer in this form of treatment. In his experience the relief of pain was one of the most constant and gratifying results of its application. Improvement was noted in cases of chronic rheumatism, rheumatoid arthritis, neuritis, and in acute local inflammatory conditions such as boils and carbuncles. It would be of interest to compare the improvement observed in the nutrition and function of paralysed limbs after infra-red irradiations with that noted after treatment with the diathermy current. A comparative series of cases would be of especial value. On theoretical grounds it seems doubtful whether the superficial heating of the tissues obtained by infra-red irradiation is likely to give results as good as those obtained by diathermy.

with rapid plate changers, will probably be unsatisfactory, showing a different degree of filling in the vessels in the two films. Asepsis demands an efficient X ray apparatus in the surgical theatre, and each side must be separately injected. In the field of interpretation there are also limitations. The arteries shown include the stem of the internal carotid and the middle cerebral of one side only. The anterior cerebrals are rarely well seen, and the posterior cerebrals are, of course, supplied by the vertebral arteries, and therefore invisible. It is, therefore, to be expected that only frontal, fronto-parietal, and temporal lobe tumours, which are relatively easy to find by other methods, will reveal their presence by displacement of the vessels concerned. The side of the lesion must previously be determined if double injection is to be avoided, and the method can give no answer to the important question whether the lesion is supra- or infra-tentorial. Ventriculography, which allows a more leisurely and methodical investigation, provides an answer to many of these questions, and also gives valuable indications at the actual operation; so the new method will probably supplement rather than supersede it. Used alone, it might, moreover, give erroneous indications. It is conceivable, for instance, that dilated ventricles displaced towards the injected side by tumour of the opposite side might so distort the vascular trunks on the injected side as to give an entirely false localisation. T. DE MARTEL,[3] commenting on eight cases examined by the method of MONIZ, says that in two of them the method gave useful information, while in the others operative verification was unsuccessful or not undertaken. He thinks that arteriography may be useful in the case of
umours which are certainly supratentorial, but
which the cerebral localisation is not precise.
It is not easy to see what advance in the diagnosis
cerebral disease can come from arteriography,
possibly it may have a definite value in the
stigation of angiomatous tumours in which
ery has little to offer at present except removal
one overlying the tumour so as to make it
accessible to radiation therapy. In the
te diagnosis and localisation of such tumours
w method may be of definite assistance,
ould show their vascular structure and thus
iate them from endotheliomata of the dura,
so reveal their presence by a bruit. In
al surgery it looks as if the field of
of the method would be narrowly
bed, but its possibilities for the investi-
he peripheral circulation should be of
he physiologist as well as the surgeon.

studies of the mental aspect of those states that are still called functional nervous disorders. Almost simultaneously **Freud** introduced a psychopathology which, in spite of its difficulties, is becoming more and more applied to the understanding of those manifestations. The study of the subject received a stimulus from the numerous psychoneuroses that arose in the late war, and a flood of popular books indicated that interest in it had reached the public; the growth of the mental hygiene movement and the establishment of special clinics are to some extent the result of the interest then aroused. As a further result many neurotic sufferers, who typically express their troubles in physical symptoms or terminology, are now ready to set aside "nerves" and its diagnostic congeners and to recognise their troubles as emotional difficulties of reaction or adaptation. Practitioner and patient are now faced with a problem, for the former's training has not fitted him to deal with this aspect, the few clinics are overcrowded, and time and expense limit the function of the specialist.

The address on the structure of neurosis given by Dr. **Alfred Adler** to the Section of Psychiatry of the Royal Society of Medicine[1] bears directly upon this problem. Dr. **Adler**, who claims for his views the title of "Individual Psychology," follows the methods of persuasion already laid down by **Dejerine** and sees in the neuroses a false solution of the problems of life, to be remedied in the adult patient by convincing him of his lack of social coöperation and training him to coöperate first with the doctor and then with others. This principle of coöperation is elaborated into an ethical system in an address printed elsewhere in this issue, but whilst freely recognising the value of ideals in social life we approach somewhat critically a claim to have solved once and for all the problem of the neuroses. If we compare **Adler**'s pathology with the matter contained in Dr. E. G. **Howe**'s lectures, now appearing in this journal, we are at once struck by its easy appeal. Science demands, says **Adler**, logic, common sense, and experience, and the experience drawn upon by him is within the understanding of any intelligent person, however ignorant of psychopathology. The difficulties of investigating and understanding unconscious processes do not exist for his readers, who are asked to do no more than judge the neurosis by the standards of everyday needs and desires. Obsessions and compulsions, phobias, morbid anxieties, somatic hysterias, all are explained by the same easily understood conception. It is a pre-analytic, a naked-eye pathology. By its aid the neurotic patient can be given a formula that covers every symptom and carries with it the lesson that his troubles are an escape from social responsibilities, and with this lesson emotionally accepted—here the physician's technique plays a part—he can be helped towards a useful life. That the formula covers only a part of the mental processes concerned, the part already recognised as the secondary aim of the neurosis, is immaterial. **Dejerine**, discussing mental and moral foundations, wrote[2]:—

> "It would indeed be altogether too naïve to think that the psychotherapist has at his command a special mode of reasoning, unknown before his time, a dialectic of invincible power. It is the confidence he inspires, it is the way of saying it, that leads to success."

We can see how the qualities, even the defects, of individual psychology meet some of the needs of the situation. Containing some essential truths, easily comprehended, all-embracing, and with the appearance of finality, it leaves no room for doubt on the part of those who accept it; the first essential of persuasive therapy is established, for confidence inspires confidence, and among the many neurotic sufferers crying out for help there is scope for the application of this simple and sometimes effective mode of treatment. Yet there is great danger in the claim of individual psychology to furnish a complete pathology of the minor, and, apparently, of the major psychoses. It is well known that **Adler**'s views owe some of their prominence to the fact that they are in opposition to those which find that sex plays an important part in the psychoneuroses. One potent factor, for example, is believed to be our emotional taboos and inhibitions, which are independent of the needs of ethical or social training and fall with especial severity upon the child. This factor either does or does not exist, and if it does exist it must be recognised, however great may be the social reaction against that recognition. For an ex-member of the Vienna Psycho-analytical Society to address a medical audience on the structure of the neuroses without mentioning sex is a *tour de force* that makes us wonder how and why it is done. Whether in its emotional inhibitions or in other ways society is responsible for thrusting upon its individual members conditions from which neurosis must inevitably result is a question to which a positive answer is likely. Recasting an old maxim, we might say that every society has the neuroses it deserves. The danger as well as the attraction of individual psychology is that it offers an easy escape from the difficulties of understanding modern psychopathology and a means by which we can avoid the consideration of probable cracks in the armour of our social self-satisfaction.

THE SOURCE OF PUERPERAL INFECTION.

It is now some years since hæmolytic streptococci were definitely indicted as the chief agent in the ætiology of puerperal fever, although other cocci, the colon bacillus and certain diphtheroids were known to cause infection occasionally. Subsequent work has only increased the weight of the charge against the streptococcus. The identification of the principal offender did not, however, complete the story of the crime, and much controversy has raged around the problem of the source of infection. A group of workers headed by Mr. **Victor Bonney** has maintained that the infection is mainly endogenous, while many others hold that it is often, primarily, or always exogenous. Recent work by Dr. JOHN SMITH at the City Hospital Laboratory, Aberdeen (summarised at p. 264 of this issue), supports those who believe that infection is generally introduced from without. He examined 18 cases of puerperal fever and three cases of septic abortion and studied the serological types of the organisms found. Of 13 cases of puerperal fever infected with *S. hæmolyticus* the strains came from an extrinsic source in 12. In no less than 11 cases of puerperal fever and one of septic abortion the infecting strains were traced to the throat or nose of the doctor, student, or nurse in attendance. Since the work of G. F. and G. H. DICK on scarlet fever, a great deal of bacteriological research on hæmolytic streptococci has been initiated. The Dicks have maintained that *S. scarlatinæ* is a special type of organism toxigenically different from other types, and other workers have claimed that ysipelas and puerperal fever respectively also have their own peculiar strains. More recent work, however, has failed to support the suggestion that the strains from different diseases produce different toxins. It has been shown that the toxins from various strains can be neutralised by scarlet fever antitoxin or, indeed, by antitoxins prepared for puerperal fever or erysipelas. It therefore seems probable that these organisms are very prevalent and that they must be harboured normally in some part of the human body. Nobody will dispute the statement that the nose, tonsil, and nasopharynx are the lair of the culprit. D. J. DAVIS declares that hæmolytic streptococci are found in from 10 to 60 per cent. of normal throats and that in susceptible persons this source of infection may cause disease through any form of contagion by droplet or spray infection.

---

[1] The Lancet, Jan. 17th, p. 136.

[2] Psychonévroses. Dejerine and Gauckler, Paris, 1911, p. 427.

The measures to be taken to prevent puerperal infection depend on its origin. Those who believe that it is due to contamination from the patient's own bowel have naturally suggested a régime of sealing-off the anus in some way. That their attempts have not been wholly successful is at least partly due to the grave difficulties put in their way by Nature herself. To attribute puerperal infection to this natural neighbour of the genital tract is to accuse Nature of a carelessness and recklessness towards natural processes that she does not often show. At one time she was accused of surrounding the birth orifice with a collection of hairs calculated to introduce infection despite the most elaborate precautions. Why 99 per cent. of women did not suffer through this mistake was never quite explained, but the hair was duly shaved until somebody pointed out that, so far from introducing infection, the hairs drained it off. This latest work of Dr. SMITH suggests that, once again, it is not the anatomy of the parts that is at fault, but the interference of man. Interference in these civilised days may be unavoidable, but it is our business to make it as perfect as possible. Dr. SMITH suggests that it may not at present be feasible to examine the throat and nose of every person in attendance, but that at least doctors and nurses might take suitable precautions by adequate masking. Any septic focus in patient or attendant should also be carefully investigated. Hospital maternity beds should be isolated by metal or glass screens and no patient should be examined or treated in the common wards. Dr. SMITH is confident enough to state that as soon as the extrinsic source of the bulk of puerperal infection is realised, and a satisfactory surgical technique is evolved, a large decline in the number of cases is bound to follow.

ANNOTATIONS

PREGNANCY AND TUBERCULOSIS.

OPINION continues divided as to how far pulmonary uberculosis is worsened by pregnancy and parturition; o what extent therefore, and at what period of regnancy, an artificial termination should be induced. ome would leave these cases rigidly to Nature, elieving that a natural delivery is always less harmful han one that is induced; others would resort to æsarean section, which affords the opportunity of terilisation at the same time. Opinion is again ivided as to the advice to be given concerning arriage, conception, and lactation; more attention hould perhaps be paid to the improbability of the dvice being taken, if it is contrary to the desires f the patient. In Gibbon's words, advice may be eeble to stem, if strong and irresistible to impel. uring latter years the induction of artificial pneumothorax during pregnancy has been sharply discussed, nd no doubt as the practice of collapse therapy xtends it will be more employed on pregnant women; our verdict on this, as on that of artificial neumothorax in general, must await the passage f time with the analysis of unselected hospital igures.

Recently H. B. Matthews and L. S. Bryant have investigated,[1] by letter of inquiry, the question of pregnancy, parturition, lactation, and menstruation in 1000 tuberculous women under comfortable circumstances. Less than half responded but from 484 replies, which were considered sufficiently full, certain conclusions were drawn. It was decided that pregnancy had a harmful effect on tuberculous women and that this was more serious if the disease was advanced. Patients who did not become pregnant until three years or more after their discharge from sanatorium, and who (on their own showing) carried out their instructions conscientiously, fared better than the others. Spontaneous abortion and post-partum hæmorrhage occurred more frequently in these patients than in the normal population. Among the live births there was an infant mortality of 4 per cent., but 91 per cent. of the survivors were healthy normal children; 71 per cent. of mothers nursed their babies. For this information we may be grateful, while recognising the pitfalls of the research by questionaire which is becoming so popular. We are not told that these patients' medical advisers concurred in their statements, for the inquiry was made from the patient herself; much might have been gathered from the story of the 500 and over who did not reply. As the inquiry concerned ex-patients only it ignored that class of case when the onset of disease occurs during pregnancy or after parturition. W. B. Hendry[2] has discussed the treatment of pregnant women and stated his belief that they should be left alone unless the lesion is active, in which case the pregnancy should be terminated during the first three months. After the first three months he regards the prognosis as grave whatever course is adopted, but it may be safer to allow the pregnancy to pursue a normal course, shortening the second stage of labour by the use of forceps or pituitrin, or by performing Cæsarean section under local anæsthesia. He sums up the situation thus: "When an active lesion is present in an unmarried woman, advise against marriage; when the patient is already married, advise against pregnancy; when pregnancy exists in the earlier months, advise its termination; when it has passed the third trimester, watch and pray." At the British Medical Association meeting held at Nottingham a few years ago R. A. Young produced a similarly epigrammatic summary: "If a virgin no marriage; if married no pregnancy; if pregnant no confinement; for the mother, no suckling."

---

[1] Jour. Amer. Med. Assoc., 1930, xcv., 1707.

At a joint meeting, reported in our last issue (p. 186), of representative obstetricians and those especially engaged in tuberculosis work, it was agreed that at least 50 per cent. of women with active tuberculosis are made iller by parturition, and that it is difficult to differentiate the effect of pregnancy from that of parturition. It is, therefore, safer for a woman with active tuberculosis not to bear children. If, however, she is already pregnant the attending physician has to decide whether the pregnancy should be interrupted or allowed to terminate naturally, bearing in mind that there are some tuberculous women on whom pregnancy has no deleterious effect, and a few whose condition seems improved by childbearing. In each case it has to be considered whether an artificial termination will be less harmful than the normal event to that patient; and here we have a conflict of evidence and an insufficient number of published cases finally to decide the point, for it is important to be guided, in this as in other matters, by actual experience rather than by the opinions of great men. If a living child is born the next problem is whether the infant should be breast-fed and for how long. It seems clear that most infants gain from breast-feeding and that the mothers do not lose, provided lactation is not prolonged. Breast-feeding should therefore be the rule unless contra-indicated in the individual instance by the risk of infection from a woman with an open lesion; the period of lactation might be limited to six months. On the liability of the children of tuberculous mothers to become infected the data are conflicting; the figures of Matthews and Bryant, referring to the 48 per cent. of good-class mothers who replied to a questionaire, can hardly be taken as applying to the bulk of the population. Nor do figures dealing with babies provide information as to their fate in later life, for they not only risk infection but also inherit a poor resistance. Other factors in the problem are worth attention. Ernest Ward showed that in 21 per cent. of 240 pregnant tuberculous women the onset of disease occurred during pregnancy or after parturition, and that of these one half died within a few years, the prognosis being far worse in their case than in those whose disease antedated pregnancy.[3] If pregnancy is to be interrupted such cases might have to be considered especially suitable. Marriage apart from conception usually improves a patient's health, and advice on contraception might be efficient where advice against matrimony would be futile. In any case, it may be better to counsel a possible postponement than attempt to impose an impossible prohibition. There must, we think, be a freer interchange of experience, some remoulding of individual beliefs, and a larger body of observed facts at disposal before valid conclusions are reached.

[3] THE LANCET, 1923, ii., 557.

AN INDEX OF RENAL EFFICIENCY.

THE drawback of most of the tests of renal function is that they require special technique or equipment. Herein lies the chief advantage of the "dilution and concentration" test. The patient empties his bladder at 7 A.M. and then drinks 1000 c.cm. of water within about ten minutes. The urine is collected hourly for four hours and then two-hourly till 7 P.M. Fairly dry food is allowed for meals but no fluid until 7 P.M. and then only enough to allay thirst. The normal kidney eliminates the whole of the ingested fluid in the first four hours with a lowering of the specific gravity of the urine to 1005 or less; after the first four hours the specific gravity gradually rises to 1020 or more. Failure to secrete the ingested fluid in the four hours or to produce a marked fall in specific gravity with subsequent rise indicates impairment of renal function. Brink[1] reports very favourably on the clinical value of this test. Buck and Proger[2] have compared it with the other tests of renal efficiency in 100 cases and find it not only more easily performed but also a more sensitive index of renal damage. They have further simplified it for the benefit of ambulatory patients, so that the only specimens of urine examined are the one passed two hours after the water is drunk and the one passed on rising the following morning. If the specific gravity of these specimens shows good dilution and concentration respectively, no further examination is necessary, but if this test is unsatisfactory the case requires a more complete investigation.

SCOTTISH FAMILY DIETARIES.

THE purely quantitative aspects of nutrition no longer occupy the pre-eminent position that they held 20 years ago. This is easily understood when we consider the striking demonstrations that have been made in recent times of the value of specific food constituents in animal nutrition. Yet the problem of how much protein, fat, and carbohydrate a man should take to maintain himself in a state of health has by no means lost its devotees. By the method of direct experiment with individuals and small groups of men it has repeatedly been shown that very great variations in the proportions of these constituents are compatible with normal health and efficiency. Nevertheless a systematic study of the amounts of these classes of foodstuffs habitually consumed by a given section of any community may be of academic interest even if its immediate practical bearing is not at once obvious. Such a study has just been reported by Prof. E. P. Cathcart, F.R.S., and Mr. A. M. T. Murray, Ph.D.[3] St. Andrews chosen for the investigation as representing a relatively well-to-do community, and among the 154 families whose household budgets were scrutinised all classes of society from the richest to the poorest were included. The diet had an average energy value, reckoned on the basis of the adult man, of 3119 calories and contained 89 g. of protein, 119 g. of fat, and 411 g. of carbohydrate. The most striking feature of this analysis is the high proportion of fat, which is more than double the amount commonly accepted as the standard for a European. Yet, curiously enough, the composition of the diets studied on this occasion is almost identical with that of the average diet in the United States. It was noted that although the amount of protein in the diet increased with a rise in the family income, the proportion of the total energy supplied by protein was remarkably constant in all the groups studied. The amount of fat, on the other hand, increased both absolutely and in proportion to the total energy value with any increase in financial resources. Further problems that are discussed include variations in the composition of the diets according to the social class and occupation of the householders and the efficiency of the parents. The general impression is gathered that the population of St. Andrews can be regarded as being well nourished, suffering neither from gluttony nor food shortage.

EFFICACY OF SERUM IN DIPHTHERIA.

FOLLOWING a complaint by practitioners in the north of France that antidiphtheritic serum, although given in larger doses, is much less efficacious than previously, an inquiry was instituted by the Commission of Serum and Vaccines of the Ministry of Public Health. The conclusion arrived at was that the serum is not to blame. J. Lignières, in a contribution to the study of the causes of insufficient activity of antidiphtheritic serum"[1] has reviewed the facts and produced some valuable comments. In recent years, he points out, the dose of antitoxin in the treatment of diphtheria has considerably increased. Thus in 1894, when serum therapy was started and for a few years afterwards, only 40 c.cm. of serum was given on the first day to severe cases, and the total injected throughout the treatment did not exceed 80–90 c.cm. At the present day in France the usual amount is about 300 c.cm. of unrefined serum. Translating these quantities into Ehrlich units of antitoxin, 1500 units were formerly given in severe cases, whereas now 100–200,000 units are normally injected and this amount is exceeded in serious cases. In the United States and Argentina still larger doses are given.

In view of the general tendency to increase even these massive doses of antitoxin, it is imperative to consider whether such large quantities are really necessary to get satisfactory results, and at the same time to remember that these results are not superior to those previously obtained with weaker antitoxin. Why therefore is a much more powerful antitoxin needed? Various suggestions have been made, based on the lateness of treatment, associated micro-organisms, the resistance of the patient, the type of epidemic, and the virulence of the bacillus. These factors which may influence any one case have always existed, and do not suggest any solution to the problem. Lignières considers that the toxin is at fault. The original serum made by Behring was comparatively weak in antitoxin, but Roux improved considerably on this, while Roux and Martin indicated the optimum conditions for obtaining the toxin. In 1894 Anna Williams isolated from a case of tonsillar diphtheria a strain of diphtheria bacillus known as Park-Williams No. 8, which for producing a powerful toxin has probably not been surpassed by any other strain. It is this strain of diphtheria bacillus which is used almost exclusively throughout the world for producing antitoxin, and which has been responsible for the extremely high titre sera obtained. But it is 36 years since this strain was isolated, and during that time it has been grown exclusively on artificial culture media. The question now arises whether its pathogenic power (as apart from its capacity to produce toxin) has not changed. Fatal cases of diphtheria have occurred in which antitoxin appeared to have no effect whatever, but organisms isolated from such cases have proved to be much inferior to the Park-Williams strain in their power to elaborate toxin. Owing to the supreme toxigenic power of the Park-Williams strain, it has been universally adopted, and no attempts have been made to replace it. Lignières considers this to be a grave mistake. He thinks that there is a distinct difference between pathogenicity for the human being and toxicity for the guinea-pig, and quotes similar examples with other organisms. The effect of successive cultivation on artificial media is to reduce the pathogenic power, and vaccines and sera derived from such organisms become less and less effective. The conclusion arrived at is that a recently isolated bacillus, though not so toxic as the Park-Williams strain, would produce a better serum, more powerful in its bactericidal action, and more efficacious from the therapeutic point of view. The bactericidal action of the serum must not be ignored, for observations have shown that in severe cases the bacillus invades the blood stream, and can be isolated from internal organs. The good results of immunisation by the anatoxin of Ramon are ascribed by Lignières to the fact that toxins from different types of recently isolated bacilli are used. He suggests therefore that antitoxin should be made from a mixture of recently isolated local strains of diphtheria bacilli. This antitoxin should be tested against the Park-Williams antitoxin now in use. The importance also of the bactericidal action of the serum should not be overlooked when treating severe cases of diphtheria.

This thesis of Lignières is worthy of the careful consideration of all who are concerned with the manufacture and use of diphtheria antitoxin.

DUST DISEASES.

IN another column Prof. Lyle Cummins relates the results of an examination of the lungs of coal-miners, in which he has been engaged for some years past. These satisfy him that the anthracosis of coal-miners is a dual condition in which the retention of coal dust in the lungs is due to a state of fibrosis indistinguishable from that found in silicosis. One characteristic feature of silicosis is however absent in the case of coal-miners—namely, the increased liability to tuberculosis. In order to explain why lungs so damaged do not more readily succumb to tuberculosis, the theory is advanced that the active principle of tuberculin is absorbed by the coal dust in the lungs—an adsorption which, it is stated, carbon particles effect in vitro. Were this so it should follow that the soot-laden lungs of city dwellers would be more resistant to tubercle than those of country folk; but mortality records point to the reverse. Even though coal-miners on the whole escape tuberculosis, on some fields they experience excessive mortalities from bronchitis which has been ascribed to the mechanical action of dust upon the larger air passages. But here also a fresh explanation has just been put forward. Prof. J. S. Haldane on Jan. 15th, before the Institution of Mining Engineers, developed the idea that liability to bronchitis depends very largely on the amount of muscular exertion which an occupation implies, and that, since coal-mining is an occupation involving much hard muscular work, it is only to be expected that the bronchitis mortality in it should be high. This idea does not account for the fact that the bronchitis rate on some coal-fields is well below normal, while that on others is far in excess. In a paper dealing with recent views on pneumonoconioses, communicated to the Epidemiological Section of the Royal Society of Medicine last week, Prof. E. L. Collis also referred to the miner; but first he pointed out that isolation of silicosis, as a specific entity with a specific cause, from the diseases caused by dust had led to close study of it and of other dust troubles. Wherever silica dust has been found as an occupational hazard, silicosis with its characteristic predisposition to tuberculosis results from it; and silica is now recognised to be a toxic industrial hazard of the first importance, however insidious its influence. Recent occupational records have shown that silicosis is not the only dust disease; bronchitis, which is usually associated with it—but may occur alone—and also pneumonia, may be equally important. Without doubt silica acts on the lungs chemically rather than mechanically; hence may arise an association between this dust hazard and diseases of the cardiovascular system, since it may induce degenerations in other tissues as well. But quite apart from such degenerations and from superadded tuberculous infection, silicosis in an advanced stage can lead to a fatal issue.

---

[1] Bull. de l'Acad. de Med., 1930, civ., 698 and 720.

Efforts to determine a safe threshold of atmospheric dustiness are placing it at about 6 million fine particles of silica per cubic foot of air. In many industries, notably in granite cutting and in mining, the replacement of hand work by pneumatic tools has led to this threshold being greatly overstepped with disastrous results, while acute silicosis has elsewhere resulted from combining silica dust with that of sodium carbonate. Once a lung is dusted with silica the condition progresses, even though exposure ceases; but incapacity may not result until a later stage, unless some infection, usually tuberculosis, supervenes. Thereupon latent silicosis is precipitated as fibrotic nodules, while the infection runs riot. The progress of fibrosis can be detected by radiography; but other dusts than silica may originate fibrosis which throws shadows indistinguishable from silicosis. Hence radiography is not, as was hoped, a sure means for diagnosing silicosis. Experiments have shown that silica dust can reactivate quiescent pulmonary tubercle, and also make living tissues a suitable pabulum for these bacilli; thus has been demonstrated that the relation indicated clinically and pathologically between silica and the tubercle bacillus has a definite existence. Recent investigations made into the possible effects of calcium dusts, particularly those arising from Carrara marble, from Portland and Bath stones, present a sharp contrast, as they exhibit these dusts as quite innocuous. Cement dust also causes but little trouble, and that little is probably due to the presence of silicates. Coal dust again seems harmless; but most coals contain more or less minerals, capable of originating fibrosis, leading to excessive mortalities from pneumonia and bronchitis. Certain coal-miners driving roads through sandstone rocks contract pure silicosis. But all forms of pulmonary fibrosis in coal-miners lead to the blocking of coal particles in the lungs, so causing anthracosis in which the coal dust acts mechanically and may convert lung tissue into solid black blocks. The lungs of miners of iron ore exhibit on the X ray screen fine generalised mottling which is coming to be recognised as a form of fibrosis distinctive from silicosis. This form is originated particularly by the dust of silicates, and is seen most definitely among asbestos workers. Although it does not predispose to tuberculous infection, as does silicotic fibrosis, it impairs the pulmonary functions even more, and in characteristic cases of asbestosis soon causes incapacity, leading on to a fatal ending. Recognition of this specific form of fibrosis, originated by the dusts of silicates, is the outstanding feature of recent work. The extent to which the whole study of dust diseases has in recent years been advanced in this country, in South Africa, in the United States, and in Australia—i.e., by the English-speaking nations—is remarkable. More than ever is it being grasped that each dust calls for special study.

EMOTION AND BLOOD PRESSURE.

THOUGH the importance of nervous factors in the causation of arterial hypertension needs little emphasis, the extent of the variation of blood pressure under stress of excitement or emotion is not so well known. In sleep and calm surroundings the pressure usually falls, but extreme temporary increases are thought to occur during nightmares, and this is generally believed to be the explanation of most of the deaths in sleep from apoplexy. In some psychoneurotic patients there is a marked raising of the blood pressure during mental stress, and clearly arterial tension varies more widely in nervous subjects than in others. As our Berlin correspondent has reported,[1] an interesting study of reactions in "normal" people was recently carried out by R. Fischer, of Vienna. Fischer[2] used as his subjects 16 male chess-players, and examined the blood pressure during and after the severe mental effort of important chess matches. He could not, however, conclude that the actual intellectual processes of chess playing caused any appreciable temporary or permanent increase of blood pressure. Emotion, on the other hand, may undoubtedly cause a rise, and the excitement of medical examination for life insurance often leads to a definite hypertension which is a source of anxiety to medical examiners. Not only is it sometimes hard to determine how far the high blood pressure is nervous and transitory, but it must also be decided what significance the instability itself possesses. There is no doubt that subjects in whom nervous hypertension is marked are often those in whom some vascular disease already exists, and in any case it appears to indicate an arterial imbalance which may possibly develop into permanent and pathological high blood pressure. In eight cases of extreme vascular instability associated with emotional hypertension, reported by E. J. Stieglitz,[3] the rise of pressure under psychic strain was in the neighbourhood of 50 mm. Hg. This rise was accompanied by definite subjective symptoms which Stieglitz compares to those complained of by women at the climacteric. Such extreme nervous hypertension he considers a precursor of true vascular disease; it is perhaps the earliest stage of "essential high blood pressure." If this is so, an undue rise of pressure under nervous stress cannot be regarded as without significance, although the imits of the normal must be difficult to fix. Certainly high blood pressure and apoplexy are often seen among those who have led anxious lives in mental rather than physical exertion, and although we cannot yet detect completely the other factors at work, it is evident that "normal" people whose blood pressures are especially liable to rise under psychical stress should avoid as far as possible occupations involving nervous excitement. But, of course, the horse cannot always be made to drink this particular water—and who blames him?

PULMONARY ABSCESS.

An improvement in diagnostic methods is often ollowed by an apparent increase in the incidence of articular diseases. Before the development of hest radiograph many conditions now recognised as mmon were regarded as rare, and it is difficult, for mple, to determine whether the statistical increase cancer of the lungs is a real increase or not. ulmonary abscess is another condition which cannot e diagnosed with confidence unless a skiagram is rthcoming. Radiology has shown that pulmonary ppuration, formerly regarded as an exceptional vent, is relatively common. In the light of X rays he teaching of Laennec that "no organic lesion is rer than a true collection of pus in the pulmonary ssue" can no longer be maintained. As I. Nanu-uscel and N. Stoichitza point out,[1] only acute lmonary abscesses could be diagnosed in the pre-ntgen era, for chronic lung abscesses were inevitably nfused with other chronic inflammatory conditions, r example, tuberculosis and bronchiectasis. On the her hand, those who maintain that there has been actual increase in pulmonary abscesses attribute to the recent prevalence of influenzal pneumonias. further suggestion that the Anglo-Saxon races are culiarly subject to pulmonary suppuration as the sult of tonsillectomies under general anæsthesia is rhaps worthy of consideration. An unhealthy nsil lying in its own bed is certainly less of a danger an it is when some fraction of its substance, or ne of its products, are transferred to the lower air ssages. It seems unlikely, however, that pulmonary suppuration is commoner to-day than it was eneration ago. The urban dweller at least breathes leaner air than did his ancestor and in general is s exposed to septic infection. It is rational to sume that any apparent increase in suppurative eumonitis is due to more precise diagnosis, and we ust insist that this is due entirely to modern methods precision, notably the application of X rays and bronchoscope. Accurate diagnosis is the essential liminary to sound treatment. And the accurate gnosis of pulmonary disease is only possible when agrams of the best quality are available, and when se are interpreted by those who have learned correlate clinical facts with radiological findings.

The first evidence of abscess formation on the ray film is the appearance of a more or less localised d uniform opacity in the lung field. The right g is more commonly affected than the left, and ppuration has a tendency to affect the middle e in the region of the fissure between the middle d lower lobes. Disintegration of the lung tissue the centre of the diseased area results in the mation of a cavity containing pus. At this stage a clear area above a fluid level surrounded by a clouded zone forms a picture that is pathognomonic of abscess. It is well to remember, however, that the cause of the abscess must still be determined, for a tuberculous vomica if it contains fluid or a cavity due to the breakdown of malignant tissue may simulate the results of ordinary suppuration.

Acute abscesses may resolve as the result of natural healing processes and leave only the evidence of a scar on the radiogram. Many abscesses do unquestionably heal in this way. The Rumanian writers quoted above are rightly sceptical of the claims preferred for various forms of medical treatment. Subcutaneous injections of emetine, of vaccines, or of chemicals, may be administered while the abscess is healing. The patient's morale may be supported and the physician's desire to participate in nature's therapy may be gratified in this way, but it is difficult to assess the results of medical treatment when nature's treatment is already at work. The wise physician will be careful to avoid doing anything which may hinder a natural cure. It is the chronic abscess that demands active treatment, and when it has persisted for two or more months surgical intervention should be considered, for the prognosis of chronic pulmonary suppuration is grave. It has been estimated that 60–80 per cent. of untreated chronic lung abscesses result in death within three or four years. Pulmonary suppuration will not remain localised, the condition will tend to spread and secondary bronchiectasis will bring further complications. Anaerobic organisms breeding in the closed abscess cavity may give rise to pulmonary gangrene and the patient's life becomes a burden. The victim of chronic pulmonary suppuration is indeed a pitiable object. His strength declines, his breathing is laboured, he is distressed by constant cough. Expectoration is copious and disgusting to his taste, while the fœtid breath he exhales is a source of almost intolerable nuisance to those who attend him and, though less directly, to himself. Operative risks are, therefore, justifiable, especially if there is a reasonable prospect of a complete and lasting cure. If this prospect is to be realised, operation should not be postponed for more than about two months from the onset of symptoms. It is hopeless, whatever methods are employed, to expect the healing of a lung that is sodden with pus. The choice of operation will depend upon the site of the lesion. Lobotomy, and drainage, lobectomy by the electro-cautery or thoracoplasty may be indicated, but it is necessary to realise that feeble measures will not suffice. Indeed, lesser procedures, for example the induction of an artificial pneumothorax, may prove more dangerous than far more radical operations. It should never be forgotten that the alternative to radical operation is a pitiful death from chronic suppuration.

AMINO-ACIDS IN PERNICIOUS ANÆMIA.

Hæmoglobin may be looked upon as a combination of hæmatin and globulin; hæmatin contains a tetrapyrrole group and globulin consists largely of histidine; histidine contains the iminazole nucleus. There is good evidence that the human organism is incapable of synthesising either the pyrrole or the iminazole nuclei, the total amount in the body being derived from ingested foodstuffs, and it is remarkable that the organism should be dependent on outside sources for its supply of these two organic nuclei which play so important a part in the formation of hæmoglobin. With this in view G. Fontes and

---

[1] Arch. méd.-chir. de l'app. respir., 1930, v., 295.

L. Thivolle[1] have recently experimented on the effect of the deprivation and the injection of these bodies in men and animals. As their source of the pyrrole nucleus they used tryptophan and for the iminazole nucleus histidine. They found that deprivation induced in rats severe anæmia and cachexia—a fact which so far as tryptophan is concerned has long been recognised. By the injection of a mixture of one part of tryptophan and two of histidine they found that they could restore health to these cachectic and anæmic animals. In human sufferers from pernicious anæmia they found that the daily injection of 100 mg. of tryptophan and 200 mg. of histidine produced a rapid rise in the blood count and improvement in the general condition; it is reported that after a month of this treatment the patients were able to carry on in a state of undiminished health and vigour for six months without further treatment. Fontes and Thivolle suggest that the curative action of liver in pernicious anæmia may be due to its containing large amounts of both of the "hæmatogenous amino-acids" in relatively simple combination, and they say that the only effective therapeutic liver extracts contain these two amino-acids in high concentration. Pernicious anæmia they attribute to a failure of the alimentary system to carry the digestion of proteins to the stage at which the "hæmatogenous amino-acids" are made available for assimilation. In support of this view they point to the achlorhydria and the digestive disturbances universally met with in this disease.

INTRAPERITONEAL THERAPY IN CHILDREN.

THE administration of fluid and drugs to young children when they are ill often presents great difficulties, which can sometimes be overcome by using the intraperitoneal route. G. C. Grulee and H. N. Sanford[2] have no doubt that fluid and drugs so given are absorbed, though the exact mechanism of absorption is obscure. They have used intraperitoneal injection to supply glucose solution in infantile diarrhœa with dehydration, in pneumonia, in pyelitis, and in post-operative illness, and they have also used it for blood transfusion, and for giving neo-arsphenamine in congenital syphilis, antitoxin in diphtheria, and colloidal iron in secondary anæmia. The possible dangers are infection of the peritoneum, pressure on the diaphragm by injection of too much fluid, and occasional severe reactions from irritation by the substances injected. We may perhaps add injury to an important organ, but this risk is not as serious as might be supposed.[3] The disadvantage is that with some substances, such as blood, absorption may be slow, though usually it is very rapid. The advantages, on the other hand, are great: oral, rectal, and subcutaneous administration of fluid in young children is often unsatisfactory and much larger quantities can be taken via the peritoneal cavity—e.g., 100 c.cm. of 5 per cent. glucose solution may be given at one injection and frequently repeated. In severe anæmia it is claimed that frequent small intraperitoneal injections of blood are easier to give and cause less severe reaction than repeated intravenous blood transfusion. H. Florey and L. J. Witts,[4] it may be recalled, came to the conclusion that in emergencies abdominal transfusion of blood is not so valuable as intravenous injection and thought it should be reserved for the more chronic forms of anæmia. Although some critics may feel that asepsis of the peritoneum is too sacred a thing to tamper with in ordinary circumstances, there are undoubtedly times when the giving of an adequate amount of fluid is a matter of life or death, and in such cases at any rate the possibilities of the intraperitoneal route should be remembered.

GRANTS FOR RESEARCH.

THE trustees of the Ella Sachs Plotz Foundation are anxious to make known the resources of their fund, whose general object is the advancement of scientific investigation. The Foundation seldom or never offers stipends to investigators, nor does it provide apparatus and materials which are ordinarily part of laboratory equipment. Its special purpose is to give grants for the purchase of apparatus and supplies needed for special investigations and for the payment of unusual expenses incidental thereto, including technic assistance. At present research is favoured which be *on medicine or surgery, and the trustees endeav* to assist workers in various countries who are trying to solve identical or related problems. Thus considerable number of grants have been made in the last few years for studies on nephritis, while interna secretion and infection have also been specially favoured. In the seven years of its existence th Foundation has made 120 grants and investigator have been aided in 15 countries. The sums provide last year for 25 different workers ranged from 200 t 500 dollars each.

Applications for assistance during the coming yea should arrive before May 1st, including statement about the nature of the research, the amount of money wanted, and the objects on which it will be spent The secretary of the executive is Dr. Joseph C. Aub Corliss P. Huntington Memorial Hospital, Boston Mass, U.S.A.

RUSSIAN SCIENTISTS AT HOME.

THE Society for Cultural Relations with Sovi Russia is considering the possibility of organising scientists' tour of scientific institutions in Sovi Russia during July and August of this year. It proposed to arrange for parties of British worke engaged in physical, biological, and medical resear to visit and meet Russians engaged in similar inves gation. "Voks," the central institution in Mosco for organising cultural relations with foreign countri is prepared to give every assistance to the tour, "Intourist," the Soviet organisation for tou parties, will consider giving specially reduced travellin charges. All those prepared to join such a tour a invited to write to the secretary of the society 1, Montague-street, London, W.C.1.

We regret to announce the death, on Jan. 27 after a prolonged illness, of Dr. Archibald Leit Professor of Experimental Pathology in the Univers of London, and Director of the Cancer Resear Department of the Cancer Hospital, Fulha Prof. Leitch, who was in his fifty-third year, recently devoted much of his time to the succ development of various methods of expe carcinogenesis. He was an enthusiastic support of the British Empire Cancer Campaign and a prominent part in the organisation of the valua Conference held under its auspices in 1928.

A POST-GRADUATE COURSE

MOTIVES AND MECHANISMS OF THE MIND.*

V.—INDIVIDUAL EMOTIONAL DEVELOPMENT.

LANTERN SLIDES.

It is desirable at this stage to get as clear an idea as possible as to the scope of psycho-pathology. Does it propose to reduce all experience, behaviour, and personality to "only" mechanisms and unconscious motives? Does it apply to everyone, sick or well, normal or abnormal, or only to those mental aberrations which are termed psycho-neuroses and psychoses?

Let us imagine for a moment that we are working a magic lantern, which has thrown on to the screen a blurred and confused image that is unintelligible both to us and to the audience. "What does this confused picture mean?" we ask. Parts of it seem to be plain, but not obviously connected with each other, and the whole is blurred, as if several slides are projected on to the screen at the same time, overlapping one another. Perhaps someone comes to our assistance, pulls a slide out of the magic lantern, and holding it up to the light says, "Look, it is quite simple. This is a straightforward picture of an Inferiority Complex." And so perhaps it is. But then another helpful person comes forward, and taking out another slide says, "This is obviously an Œdipus Complex, and those things are only phallic symbols." Then there are others, who each discover different slides. One says, "The man is a thinking introvert, and that accounts for everything." Another says, "Recapitulation mechanism." Another, "The man is hyperthyroid with an over active sympathetic system." Another, "He is toxic: look at his teeth." But each is liable to see only the one slide which he is examining, whereas the truth was in fact just that confused picture which was on the screen, showing the sum of many factors, which was the man's life as a whole. Each slide was in fact included in that whole, but it was not the only one.

Let us try to generalise about these "slides," and classify them a little, to show of what factors each individual life is composed. In other words, we can sort out the confused picture which each individual life presents by analysis of its component motives and experiences.

The first "slide" which we must look for is *individual experience*, the particular factors of environment which have influenced development in each particular case. Remembering the importance of "transferred affects," we can analyse back from the value of "this, now" to the cause in an experience of "that, then." This slide seems to be complete in itself, developed in continuity and by association, but it is not all of a person's life and character, and leaves much still to be understood.

The second slide is *recapitulation*, and is something quite separate and distinct from the first. It does not refer to individual experience, but to the expression of inborn racial factors, which seem to be quite independent of experience, and conform to general types. Both what we fear and whom we love are influenced by recapitulation, as well as by experience. Recapitulation therefore makes our understanding of life infinitely more complex, because it introduces deeper factors independent of personal experience.

The third slide which we may expect to find is that of *type*, which is a matter of great importance in individual variation. The best classification of types is that of Jung, who divides people into (*a*) extraverts, (*b*) introverts, each again divided into (1) thinking, (2) feeling, (3) intuitive, (4) sensorial as subjunctions. This is in itself a very large subject, and readers who are interested in pursuing it further are referred to Jung's "Psychological Types."

The fourth slide is due to *physical factors*, such as endocrine variations (e.g., thyroid, pituitary, gonad and adrenal excess and deficiency) or toxæmia from any source.

So far our analysis may be mathematically logical and determined. We may examine each slide separately, and say, "This is only a form of that, and has been produced in such a way, having been irrevocably determined and caused by so and so." Much analysis seeks to be of this mechanical and final kind; but is it then complete in its understanding of the individual, his character and behaviour? Or is there yet another slide, an original unique individual potentiality, distinct for each one of us, and not able to be analysed or defined any further? It may be regarded as being a difference of quantity or of quality, but we must allow for its existence, and accept it as the basis of our technique and the limit of our therapeutic success. Analysis cannot change fundamentals, or make "Silk purses out of sows' ears." It can only make the best use of the potentialities of each individual's innate endowment, and with that limitation it must be satisfied. We may call this last slide a *unique individual integrative and dynamic factor*.

Finally, we see that these five "slides" may be applied to everyone, well or sick, normal or abnormal, sane or insane, psychoneurotic or psychotic. But it is obvious that psychopathology will occur to a more marked degree in the sick, the abnormal, and the insane. The difference, however, is only a matter of degree, and we may expect to find our knowledge and understanding of our patients greatly increased and simplified by our knowledge of ourselves, our motives, and our behaviour.

Undifferentiated Ego.

We must now go back to the beginning of the individual life and enter, so far as we are able, into the world of the infant. A good deal of stress has been laid in some psychological quarters upon the baby's first experience, that of birth. There can be very little doubt that the more or less sudden change, from a life of complete tranquillity within the womb to the very different outside world, must come as a rude shock, towards which the first cry is an appropriate expression of feeling. As soon as this is over and the baby safely bestowed between the warm blankets of its cot, it has become more nearly restored to the earlier state of peace and tranquillity, except, however, for the urge of hunger. Warmth may be provided by the blankets, but the satisfaction of hunger requires food in quite a new way from that to which the baby has in the past been accustomed.

Before birth the state of the baby must nearly approach Nirvana in its feelings of bliss, peace, and omnipotence. Every need is supplied without effort, and the fœtus is protected from every external shock and danger. With birth comes a rude awakening, and the baby realises its first sense of *deprivation.* Food can now only be obtained at intervals and with a considerable degree of effort. Certain functions are expected of it and it is surrounded by unaccustomed stimuli. Every detail of life is a new experience and the constant struggle with environment, which must continue until death, has begun.

---

* A course of 12 lectures delivered under the auspices of the Tavistock Clinic, Tavistock-square, by Dr. E. Graham Howe during the autumn session of 1930. Earlier lectures of the series have appeared weekly in THE LANCET since Jan. 3rd.

If we are to put in words the state of satisfaction which the fœtus must feel in intra-uterine life, we do so as a comparison with the changed state which must follow upon birth. Within the uterus the fœtus possesses a "limited omnipotence"—i.e., the immediate satisfaction of desire and a complete sense of safety. When it is born, the omnipotence has departed, familiarity and safety give place to novelty and fear, and the satisfaction of desire has to be postponed to suit the convenience of others. Development has taken place by deprivation and this earliest lesson of gaining by losing is only the first of many more which are to follow. The sense of *deprivation* gives rise to feelings of *resentment* and *rebellion,* and would seem to account for all the behaviour disorders of earliest infancy. The infant does not give up its prerogative of omnipotence without a struggle.

In the beginning, the world of the infant is only a large undifferentiated "me." There is no distinction between "me" and "not me." This is termed the condition of the "undifferentiated ego." Differentiation takes place through a gradual realisation of deprivation and a progressive distinction between what is "me" and what is "not me." In the beginning there is no difference between "my mother" and "me." She exists only as a source of gratification of my feeling of hunger, and her nipple is as much part of "me" as the mouth which receives it. The lesson of deprivation is an early one and gradual distinction is made until awareness of the limits of one's own ego is finally acquired. For the rest of our lives, however, we may be said to be struggling against our limitations, struggling as it were to fulfil our infantile conception of undifferentiated ego and effortless omnipotence. We rarely entirely give up the illusion of this extended possessiveness, and our passion for property and power in later life is often only a recrudescence of this infantile longing.

Let us try to trace the sequence of this development from the beginning to the end.

1. In the beginning is "me." *I feel* and *I wish.*
2. Then comes differentiation between "me" and "not me." "I feel *it* is not *me.*" This is accompanied by a sense of deprivation.
3. Experience of what is "not me" leads me to know what I feel about it (the *sense* of it).
4. I can then learn to know what "it" is, distinct from what I feel about it, and as having its own independent existence apart from me.
5. I make use of what is "not me" where I can to fulfil and satisfy "me." I can thus eventually get over my initial sense of deprivation.

GROWTH.

We must now define what we mean by psychological *growth.* It is the process of emotional development, which on the one hand occurs according to the pattern of recapitulation, and on the other results from interaction between individuality and experience. It is partly a consequence of the development of an inborn pattern due to past racial experience according to the law of recapitulation. It is partly a consequence of the individual's experience of interaction between himself and his environment. It begins with a differentiation between "me" and "not me," and proceeds by continuity and association, selection and integration, to the completeness of individual character. The dynamism of growth operates from within outwards, according to certain instinctive urges and through associated emotional states. Growth is a progressive distinction between "me" and "not me," in which the focus of interest is in the first place ego-centric and finally cosmo-centric. Self-expression and wish-fulfilment are achieved through manipulation to our ends of an external reality, which is viewed as something objective and independent of ourselves.

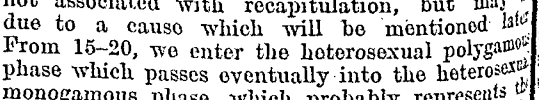
Failure in the development of individual character may be due to two distinct causes:

1. *Defective material* may cause an inborn weakness of individual constitution.
2. *Environmental factors* may thwart and overcome innate tendencies and potentialities. In either case it will be seen that the defect is due to a failure of individual growth to overcome the resistance of the external environment. The struggle between the two is a relative one, in that the lesser individual constitutional strength will only be able to cope with a less difficult environment, whereas the stronger constitution can succeed in the face of greater difficulties. It may be said that some character defects are born, but others are made by environmental influences. As Freud has said, some patients would have been ill in any case, but others under easier circumstances might have remained well.

Recapitulation Scale.

It is now necessary to correlate individual development, through experience and association, with what was said in the previous lecture about recapitulation. Individual emotional development and recapitulation take place, as it were, one overlaid upon the other, recapitulation being the underlying principle which is all the while being modified by experience.

FIG. 1.



In the above diagram† the earliest phase of emotional development, 1–3 years, is correlated with recapitulation of the endogamous racial phase. The homosexual phase, from 10–15, is probably not associated with recapitulation, but may be due to a cause which will be mentioned later. From 15–20, we enter the heterosexual polygamous phase which passes eventually into the heterosexual monogamous phase, which probably represents the highest level of sexual adaptation, both for the race and the individual.

Emotional Development.

In the following scheme it is proposed to limit our consideration to the male for the sake of simplicity. In a subsequent lecture some attempt will be made distinguish between the differences of development and general psychology of the sexes. To a large extent the principles will be found to hold good for both sexes, although they sometimes appear to be considerably more clearly shown in the male than in the female.

---

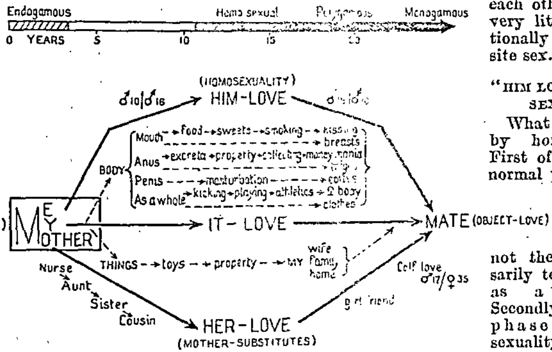
† A word of warning is necessary about these diagrams. They are only of use in such a subject as this if their value, very strictly limited. They are not intended to be actually representative of what occurs, but only to suggest a scheme to simplify our understanding. Any diagrams in these lectures are therefore put forward tentatively as the nucleus of a framework upon which to hang ideas, and too much must not be expected of them.

Let us be quite clear again as to the starting-point of emotional development. Essentially it is a state in which "I love myself," and "myself" is in the condition of undifferentiated ego. The infant's interest in life is determined by what he can get out of it without putting anything into it. He is entirely ego-centric, self-willed, self-loving and self-centred, competitive rather than coöperative, possessive and keenly resentful of dispossession. At the other end of the emotional scale, which may be described as "emotional maturity," the opposite is found to the case. Instead of self-love we have a state of object-love; instead of being self-centred we are object- or cosmo-centred. Altruism has taken the place of self-will and self-love, and a coöperative attitude that of the competitive. A completeness of differentiation has taken place between "me" and "not me" in which the possessive, competitive attitude is replaced by the sharing, coöperative one. All this takes place through normal development and growth.

By what process of development and through what tages is this change achieved? In its simplest orm, the continuity of the process is suggested in he accompanying diagram (Fig. 2). The initial state f undifferentiated ego is represented by the three racteristics of "me," "my" and "mother," at his stage only potentially distinct. This is the rimary goal of the earliest love feeling, and is elf-love. At the other end of the emotional scale the *potential mate*, the goal of sexual object-love. he purpose of the diagram is to show the continuity f development between infantile self-love on the ne hand, which is competitive and possessive, nd mature sexual object-love upon the other hand, hich is altruistic and coöperative. Both of these ust, of course, be regarded as theoretical abstractions bject in practice to individual modification.

As we proceed from left to right of the diagram, evelopment roughly corresponds with the recapitulaon time scale which is placed above it. The principles f *continuity* and *association* must be preserved and order to get from A to Z we have to proceed through intermediate phases represented by the other letters f the alphabet. In the beginning we have a state f "me love," in the end a state of "mate love." What are the intermediate steps? The intermediate ource of emotional interest would be partly "me ove," partly "object-love"—someone who is like me ut not me, yet someone who is also like the mate ut not the mate. This condition is fulfilled by what is called on the diagram "him love," reached in the adolescent phase of homosexuality, say between 10 and 15. "He" is like "me" being of my sex; but he is not me. In the early phase of homosexuality the emotional interest is usually of a younger boy for an older one, say of a boy of 10 for a boy of 16. In the later phase, however, the condition is usually reversed, the boy of 16 tending to be more attracted to the younger boy and the emotional position then corresponds more nearly to what will ultimately become mate love. The younger boy is more nearly in the feminine rôle of dependence. It is characteristic of the homosexual phase of early adolescence that normally boys should only be interested in each other, and have very little use emotionally for the opposite sex.

FIG. 2.—*Emotional Development (Male).*



"HIM LOVE": HOMOSEXUALITY.

What do we mean by homosexuality? First of all, it is a normal phase associated with adolescent development and is not therefore necessarily to be regarded as a perversion. Secondly, the normal phase of homosexuality is independent of any overt sexual expression. This, when it occurs, may be regarded as a pathological expression of a physical sexual factor, but seeing that the normal phase of homosexuality occurs at the same time as the sexual glands are developing, it is not surprising that some overt practice of homosexuality does often take place amongst boys, the most common being, as would be expected, the practice of mutual masturbation, with more or less pronounced differentiation of masculine and feminine rôles.

The following classification of homosexuality may be suggested:—

1. Physiological.
2. Psychological.
   (*a*) Normal phase
   (*b*) Fixated— (1) Sublimated.
   (2) Overt.
   (3) Repressed.

In *physiological* homosexuality, the bisexuality which is physiologically present in all men and women to a greater or less degree usually shows some evidence of those characteristics which are associated with the opposite sex. In the more obvious cases of male physiological homosexuality the physique and behaviour is strongly suggestive of the feminine type, with a tendency towards prettiness, passivity, and timidity. Physiological homosexuality is an individual predisposition and is very rarely amenable to successful psychological treatment.

Psychological homosexuality is the more frequent of the two. In these cases the feminine characteristics are usually lacking, but the choice of object-love remains towards a member of the same sex. Such cases offer a far greater hope of satisfactory treatment.

Psychological homosexuality may be divided into two phases: (*a*) normal phase, (*b*) fixated. The *normal phase* of psychological homosexuality occurs in adolescence about the years 12–15. It is very common, however, in the absence of opportunity for heterosexual self-expression, for the homosexual phase to persist beyond adolescence up to 20 and sometimes 25 or even later. Young men of this age are often aware of the attractiveness of boys of their own sex, while being at the same time also susceptible to feminine attractions. It is as if the usually brief homosexual phase persists in the absence of complete heterosexual opportunity for development. Such men when they marry usually become fully and normally heterosexual without any difficulty. Sometimes heterosexual development does not take place, however, and the condition is then referred to as *fixated*, and is liable to show itself as what is known as *perversion*. The possible causes of such a fixation will be referred to later.

Homosexuality may occur in any of three ways. It may be: (1) sublimated, (2) overt, (3) repressed.

Sublimated homosexuality is a normal and desirable emotional activity of adolescence, and occurs without any overt sexual expression. The tendency of boys to seek only each other's company, to associate in clubs, packs and gangs, and to be completely intolerant of and indifferent to the female sex, is the normal expression of this phase. Sublimated psychological homosexuality is the attitude of the normal schoolboy. After heterosexual development has taken place, sublimated homosexuality remains of great importance as being the tie which binds men in friendship, and through which they enjoy each other's company in clubs, masonic gatherings, and the everyday intercourse of business and social life. The homosexual impulse is therefore of great importance in regulating and inspiring social behaviour.

Overt homosexuality finds active self-expression with a member of the same sex sometimes by the practice of mutual masturbation, often by the more sexually differentiated form of intercrural intercourse. When it occurs this may be regarded as a perversion, but in the absence of the teaching of the elements of sexual hygiene and development it is not really to be wondered at, and need not be considered seriously pathological, although it is certainly morally and psychologically undesirable. The comparatively very rare perversion of intercourse *per anum* is a sign of fixation at the earlier anal-erotic level, which will be referred to later, and is a far more serious though much less frequent problem.

Repressed homosexuality is a matter of great importance because of the unconscious influence which it brings to bear on the subject's attitude towards others who possess a similar tendency. It is only natural to expect that the choice of the scholastic profession is largely determined by a man's degree of emotional interest in boys. It is therefore also to be expected that there should be an increased degree of homosexuality amongst schoolmasters, but without any opportunity for its overt expression. It must be repressed, and this causes certain consequences. It can only be repressed by the individual regarding it as a very serious misdemeanour in himself and therefore in others. Intolerance of homosexuality is a defensive mechanism required to preserve its repression and the observance of moral standards. Schoolmasters as a whole, therefore, are very liable to be unwisely intolerant of masturbation and homosexual practices, and are inclined to regard them with undue severity when they are discovered amongst their boys. Their attitude is inclined to be drastic and punitive and the punishment unwarrantably severe.

Repressed homosexuality presents a problem which it is difficult for the moralists to answer. There may be no outward expression of homosexuality at all. On the contrary, the individual's life may be lived according to the highest moral standards, but it may still persist. A great many marriages are wrecked owing to the fact that one partner is a repressed homosexual and therefore sexually intolerant of the other. Heterosexual union may take place with the subsequent birth of children and yet repressed homosexuality may persist, of which the following is an illustrative case.

CASE O.—Married. Aged 52. Three children. Occupation: master tailor.

Symptoms: Excessive anxiety, intense feeling of guilt and delusions of persecution (paranoia).

History: The symptoms had developed about two years previously in the following circumstances. The patient had been discussing with his friends a case at the Old Bailey of homosexual practice, but he found that he could not get the case out of his mind. He thought people were accusing him of homosexual practices, and, although he had never been guilty of them, he felt an extreme sense of guilt. He imagined that people who passed him in the street were making accusing remarks about him, and this state of affairs caused him intense anxiety.

As a boy he was entirely innocent and ignorant of sexual matters. He was apprenticed to tailoring and his combination of skill as a cutter, with his social aptitude, made his business a great success. People used to go to him as much for his friendship as for the quality and cut of his It may be imagined that his contact with those of his own sex, measuring and fitting, &c., gave him considerable outlet for homosexuality, although it was to him entirely unconscious.

When he married he was quite ignorant of sexual matters and he chose a very timid and invalid wife, by whom he had three children. He was a very enthusiastic social worker in connexion with the church, in which he held at various times all the responsible positions open to a layman. He was very rarely at home in the evenings but always the company of his friends.

Analytical investigation proved the existence of homosexual impulse, which had never been conscious overtly expressed. Its existence seemed, however, to have determined the subsequent insanity from which he did not recover. His sense of guilt applied not to what he had done, but to what he unconsciously wished to do, and the repression of his homosexuality ultimately came out through the mechanism of his delusions.

"HER LOVE."

The lowest line of the diagram (p. 259) is that which proceeds from the beginning "I love my mother," to the end "I love my mate." Again it is neces to preserve continuity and association. "She must be someone who is like my mother but not my mother, like my mate but not my mate. This line preserves the heterosexual continuity and is the line of "her love," the loved object being more or less a *mother substitute*. The transference of emotional regard shifts in turn to various associated mother figures, the first probably being the nurse. The strength and weakness of the position of the aunt in the family lies in her near association to the mother. At a later phase, the cousin is of importance as being the last emotional link with the family. She is still in the family, but is so nearly outside it as to become very near the potential mate. What is known as "calf love" occurs when a boy of 16 or 17 finds his most loved object in a woman of mature years, 35 to 45. The cause of this lies in the fact that her age and maturity remind him of the origin of his love feelings, his mother. In the final adjustment of the man to the mate, there is usually not a little of this "mother-love," but it can easily be too much for matrimonial harmony. "All husbands need to be treated like children sometimes." But a true mating involves a loosening of many bonds, of which the most important is complete unbinding of the maternal apron strings. If all parties in matrimonial experience realised this simple fact of human psychology, many marriages would be happier than they are.

"IT LOVE": PROPERTY FIXATION.

The third potential division of undifferentiated ego comes from "my" love. This may be divided into two: *my body* and *my things.* The part of the body which is of primary emotional significance is *the mouth*, by its association with the maternal breasts and the infantile food-supply. Sucking is therefore an activity of great importance, from which is derived a large amount of emotional gratification. Through what line does this continue and through what associations is it maintained? We find an intense interest during the whole of life in food, exaggerated in some cases such as the glutton, the gourmand and the gourmet, in all of whom the importance of food as a means of gratification is more than it should be. Eating sweets comes into this line of continuity and association, and is particularly an activity of childhood and adolescence. After adolescence the sweet-sucking tendency gives place to that of cigarette and pipe-smoking, which is probably an extension from the primary sucking gratification. A more definitely sexual derivative of this oral source of gratification (known technically as "oral erotism") is kissing, which is of ultimate significance with regard to the mate.

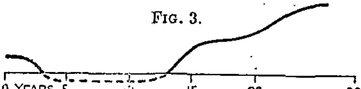
The next part of the body which assumes importance as *a source of gratification is that which is* associated with the alimentary excretory function—i.e., *the anus.* The degree of interest which the infant takes in its excretory function is rather surprising, but it is quite definite. Perhaps this interest has become exaggerated owing to the importance attached to it by mother and nurse from the beginning. It is rather strange to realise the extent to which the excretory function is associated from the beginning with the moral concepts of good and evil. A child is "good" whose bowels function regularly at the behest of mother or nurse, and the child is "bad" who fails to do so. From the first day the child is born, the ordered exercise of this function is expected, and for the most impressive years of life it is associated with the moral qualities of good and bad. Besides the moral aspect there is also a more physical aspect of "well" and "ill," and it is perhaps for this reason that alimentary function may develop an exaggerated importance even in general medicine. If our bowels have not been opened we feel "bad" or "ill," and probably a large part of this feeling has been built up by association and continuity from the values inculcated in us from infancy and childhood. The alimentary function is important, but not to the degree which we unconsciously ascribe to it. To some it assumes an exaggerated importance and the tendency to rebellious independence may show itself in the development of intractable constipation, which is therefore in such cases of psychological and not physiological causation.

It has been suggested that another derivative by association of this "anal-erotic" interest is the habit of collecting, best exemplified in the case of the miser. In this case money has become the symbol of a primary anal-erotic interest in fæces. It is also suggested that all collecting manias originate from this source, although they may be as varied in object and degree as the obsession of the miser, or the highly sublimated interest of the collector of objects of art.

A more definite derivative in simple continuity is the erotic gratification derived from the thighs, corresponding to the oral gratification derived from the breasts, of the loved one.

Early in the second year the *penis* is an object of possessive interest and pride, and it is also sometimes a source of gratification by masturbation in infancy and early childhood. It is again associated in the first place with its excretory function, and children *often take great interest in urination.* It is not, however, until puberty that it becomes of dominant importance, with the physiological development of the gonads. It is the greatest possible mistake, however, to think that sexual development commences at puberty. *The sexual function of puberty is only a continuation of all antecedent sexual function,* which has begun not only in the individual lifetime, but also in a far-distant racial past.

FIG. 3.



Development of sexual function.

The above diagram shows the way in which sexual function and interest tend to be latent from the period of about 3 to puberty, but the sexual feelings of puberty are all derived from earlier infantile sources.

MASTURBATION.

The first thing to recognise in consideration of *masturbation* is, *in the absence of adequate sexual instruction*, its logical inevitability. Nature has been unduly prolific in its endowment of the human race with the sexual procreative urge, and it is in adolescence, with the development of the sexual glands, that we must expect a sudden development of sexual interest and activity. It is possible to keep children ignorant, but not "innocent." The sexual factor is *an inborn urge of great intensity* and, when associated with a healthy curiosity and the normally developing phase of homosexuality, it is not surprising that masturbation should occur in males at some period of their lives. It is, of course, impossible to give accurate figures, but authorities put its frequency at over 95 per cent.

If masturbation is so logical and inevitable, why is it always accompanied by such an intense feeling of *guilt?* Even where it is practised without apparent self-restraint, there is always an underlying guilt sense, and it is owing to this that the practice of masturbation is *psychologically injurious. In spite* of much that has been said to the contrary, it is not *physically* injurious unless practised to excess. It is difficult to define "excess," as this must of course involve an individual factor, but it frequently occurs daily over long periods without giving rise to physical injury, although on the *psychological side* there is always a loss of self-respect and strength of character. It is quite impossible to be so frequently overcome by impulses to do what one feels to be wrong, without suffering in strength and coördination of character. But in spite of this it is quite untrue to say that masturbation *causes insanity. It is primarily* a symptom, not a cause, although it may secondarily become a cause of various degrees of anxiety.

The guilt of masturbation is due to a "transferred affect" from which all our sexual feelings are afterwards inclined to suffer. The origin of these sexual feelings, being associated with the mother, takes its guilt from that source and the guilt of masturbation is a transferred affect from the primary incest motive. It is common for patients, and sometimes boys also, to feel that they have committed the "unpardonable sin," and this association of extreme guilt is derived from the incest motive. In a later lecture it will be suggested that the Holy Ghost is a derivative of the mother figure, and the "sin against the Holy Ghost" is therefore an unconscious link with the primary love for the mother.

We can now understand why the idea of *punishment* is so frequently associated with the guilt sense of masturbation. Well-meaning pamphlets written by ignorant propagandists stress the terrible consequences of the practice of masturbation, which they say causes physical diseases and insanity. Unfortunately it might be said with some truth that these well-meaning pamphlets have done more harm, both physically and mentally, than ever the practice of masturbation has done, by exaggerating fears of punishment which are already present in the individual; unconscious feelings. The unconscious pattern is to connect guilt with punishment and it needs no pamphlet to help us to do so. These pamphlets are only a defensive "projection" from the writer's own feelings of guilt, and they do nothing towards the elucidation of what must always be a difficult problem. There is no doubt that feelings of guilt and fear are inborn tendencies capable of causing great harm, which require to be eliminated, not exaggerated. Exaggerating guilt and fear, however well-meaning, is always harmful and prejudicial to normal development.

THE BODY AS A WHOLE.

There is a very real gratification to the infant in the exercise of his limbs. Happiness is to lie naked with every movement of arms and legs free and unfettered. This satisfaction of free movement is the source from which is afterwards derived much of the pleasure of athletics. Running about on a football field is in continuity with the untiring activity of the child who never wishes to keep still.

The *body as a whole* is a source of pleasure, especially in a state of nakedness. "Exhibitionism," as it is called, is frequently found in small children, who may suddenly be discovered with no clothes on at all enjoying themselves intensely. In early childhood it should not be taken too seriously, because repression of it is liable to give rise to those cases of impulsive exhibitionistic self-exposure, which may occur as a perversion in later life.

The affect may be transferred from the body to the clothes, and the "dandy" is a person whose exhibitionistic self-love has become at least partly transferred to his sartorial elegance. The ultimate conclusion of this line of love interest is fulfilled through the delight in the clothing and body of the beloved.

"PROPERTY FIXATION."

The second division of "my love" is derived from those things which are mine, apart from my body. In the first place these are "my toys," about which the child is inclined, in the beginning, to be exclusive. A great sense of power and personality becomes associated with property however insignificant the property may seem to be. The contents of a boy's pocket, to the superior adult, may seem to be trivial, but the collection of string, stamps, foreign coins, clasp knife, and other "rubbish" represent to him symbols of the utmost significance which are in no way to be treated lightly.

Our sense of personal valuation, which it is very often hard to achieve owing to adult superiority, is easily extended by our possessions, and their quality and quantity may come to be taken as a measure, quite wrongly, of our personal prestige. The person who is so proud of his wireless set is often using it as a means of extending his own personal value. It is not merely a wireless set, it is a part or expression of himself. "It is perfect, it is mine, it is me." Pride of possession in a new car is also to a large extent the expansion of the owner's ego. "It is my car, it is me. It is a very fine car, therefore I am very fine." The person who requires to raise his prestige through the possession of a two-seater coupé Rolls-Royce is probably in need of a great deal of over-compensation for his feeling of inferiority. These are all examples of "undifferentiated ego" and of failure to distinguish between what is "me" and what is "not me."

A certain type of early-Victorian parent was an example of this attitude of property fixation and undifferentiated ego. He adopted the patriarchal attitude of possession of his tribe and permitted very little individuality to its members. His wife decorously submitted; his sons were appointed to their respective professions of the Church, army, or navy; and the daughters were so many elegant appendages to the family tree. "Property fixation" is always possessive and exclusive, denying the individual rights and freedom of others. It is interesting to surmise that this has perhaps been partly the cause of the development of the present commercial system, which would suggest that the state of our economic development has also not progressed much beyond an early emotional level.

The parent of mature emotional development values himself for what he is and each individual member of his family for what they are, independent of himself. He is not patriarchal, dogmatic, or possessive, and is not intolerant of the divergent views of different sexes at different ages.

Narcissism.

It is interesting and useful to give a more definite psychological meaning to the three words—pride, conceit, and vanity. We are *proud* of a heritage which we have not made ourselves—e.g., our school, our family, our country. There is no undifferentiated ego in pride. It is impersonal. We are proud of our bodies, our physique, and our health, but we are not "self-made men." Pride is a consequence of ego differentiation and is therefore entirely free from vanity or conceit. It is the only one of these three words, which, used in this sense, represents an unqualified virtue. True pride is always humble because it is impersonal, and it seeks to gain no personal value out of the object of its pride.

Conceit is associated with shyness and is an over-compensation for a feeling of inferiority. The conceited person takes every object of undifferentiated ego that he can to add to the stature of his prestige. He needs it all, because of his fundamental lack of self-respect. It is not abuse or even criticism that he requires, so much as some measure of real achievement which will add to his self-respect. Conceit and shyness are the twin horns of the dilemma of the inferiority complex and are always signs of an undeveloped and unstable emotional synthesis.

Vanity is the everyday word used for the more psychological one of "Narcissism." It is different from both pride and conceit. It is personal self-love without that feeling of inferiority and its over-compensation, which is characteristic of conceit. The vain person loves himself without criticism, admiring himself in every reflection which he sees and expecting to be admired in the same measure by others. Narcissism is an unqualified expression of self-love and the vain person has not developed far on the emotional scale. He is the god of his own idolatry.

Sex: Its Source and its Derivatives.

Those who wish to criticise modern psychology usually find cause to do so in what they call its sole preoccupation with sex. From what has already been said it is obvious that the general attitude towards sex must be to some extent uneducated and unconsciously based upon motives of guilt and fear. Any true valuation of sex must be independent of unconscious sources of guilt and fear, and will therefore arouse a great measure of unenlightened criticism from those more subject to unconscious motives. On the other hand, a part of the criticism is probably true. Psychology is still somewhat new and unbalanced and it is probable that the sexual factor, neglected for so long, has now received undue importance which time will tend to correct.

Our great difficulty in getting a true estimate of what we mean by "love" is that our use of the word covers such a large range of experience. On the one hand there is the religious conception of love, on the other the sexual, and for the two we use the same short word. Even in sexual love there are the extreme limits of Narcissism and mature mate-love. We can only begin to see the problem in its true perspective when we realise that it is one of growth, the beginning of which shows very wide variation from the end. It is as if both the acorn and the oak tree were described by the same word, in spite of their obvious disparity.

The infantile undifferentiated ego is only interested in self-love, and like the acorn, represents the beginning from which growth develops. Altruistic object-love, with all its extensions and associations in relation to sex, represents the mature development of the oak tree. Sex is only one aspect of emotional development, but it is the source from which arise by continuity and association our feelings for all the people and objects we love. Sex is a limited focus of love and the sex activity is a limited development of the love-life, which is capable of expression in innumerable other forms. The function of sex is the all-important one of reproduction and the continuity of the species, but it would also seem to be only the procreative aspect of a greater theme. The greater theme is the urge for development, growth, progress. Love is the builder, not only of individuals and families, but of races, causes, and of all creative and artistic effort. When we get our perspective of sexual life in some degree of order we can see the beginning, but we cannot see the whole because the ultimate potential development is so far beyond. Sex is not all of love. but it is the beginning, and in order to understand the end it is necessary to know something of the beginning also.

Our view of life generally suffers from being unduly anthropomorphic. Love is not necessarily the tender emotion of our sentimental fancy, as its beginning in intolerant and competitive self-love proves. "Nature red in tooth and claw" is an example of an early phase of self-love, competitive, exclusive, and self-centred, but nevertheless as a beginning it is in ultimate continuity with the highest level of self-development. Love is the force which both preserves and develops the individual, and at the same time defines his attitude towards others. Love is the urge towards all coöperation, synthesis, and growth, and is not in itself necessarily a human characteristic. What we see of love in human life is only its human aspect and what we see of love in sex is only the sexual part of its human aspect. The essential principle of love would seem to be independent of sex, independent even of the human race. Is it not the force, the primal urge, of all that grows and is creative in life?

APPEALS BY VOLUNTARY HOSPITALS.

In The Lancet of Dec. 27th, 1930 (p. 1425), ppeared a tabulated list of voluntary hospitals making special appeals. The list was known to be ncomplete, and it was stated that a further list would be published if notice was received from other hospitals appealing for funds for some special purpose. The following hospitals have asked to be included in this list.

The list shows that apart from appeals for maintenance, the voluntary hospitals throughout the country are in need of well over three million pounds for developments, extensions, and, in some cases, for entire reconstruction.

TABULATED LIST OF HOSPITALS WITH SPECIAL APPEALS.

Name of town and hospital.	Date of appeal.	Amount required.	Amount received.	Purpose.
		£	£	
SHFORD Hospital	1925	40,000	34,700	Debt on new hospital.
BEXHILL Hospital	1926	33,000	24,000	Debt on new hospital.
BIRMINGHAM Hospital Centre ..	1930	1,250,000	590,000	New hospitals and medical faculty.
ROMER and District Hospital ..	1929	20,000	14,500	New hospital.
DERBY: Derbyshire Hospital for Sick Children	1928	22,000	11,000	New wards and new nurses' home.
ONDON:				
The Princess Louise Kensington Hospital for Children..	1929	25,000	3,000	New nurses' home and administrative offices, to free ward space for 42 cots.
Tavistock-square Clinic for Functional Nervous Disorders	1930	400,000	7,000	Extensions.
MIDDLESBROUGH: North Ormesby Hospital	1929	30,000	28,500	New operating theatres and wards.

SPECIAL ARTICLES

THE SOURCE OF INFECTION IN PUERPERAL FEVER.

IN 1928 the Scottish Board of Health published a report by Dr. J. Parlane Kinloch, Dr. John Smith, and Dr. J. A. Stephen, entitled "Maternal Mortality in Aberdeen, 1918–1927, with Special Reference to Puerperal Sepsis." The reporters concluded, inter alia, that in puerperal sepsis, as in other streptococcal diseases, the essential mode of infection is by contagion (the term "contagion" being understood to embrace all the channels by which any droplet or spray infection is spread); and that an important factor in contagion is a streptococcal carrier condition in physicians, nurses, or patients. The same department now publishes a report by Dr. Smith on a routine bacteriological investigation of 221 cases of puerperal fever and 25 cases of septic abortion occurring in Aberdeen over a period of eight years, and an inquiry into the source of infection in 18 cases of puerperal fever and three cases of septic abortion.[1]

For eight years all cases of puerperal fever admitted to the Aberdeen City Hospital for Infectious Diseases have been made the subject of a routine bacteriological investigation. Blood and uterine cultures were made and any pus obtained was examined. The organisms secured were identified by the usual morphological and cultural tests, and when necessary the hæmolytic activity was examined after growing in 10 per cent. horse serum broth for eight hours at 37° C.

Of 196 cases the infecting organism was *Streptococcus hæmolyticus* alone in 120 cases, and *S. hæmolyticus* with other organisms in a further 29 cases. Three cases had sterile uterine swabs, and the remaining 44 showed *Bacillus coli*, *B. proteus*, staphylococci, gonococci, pneumococci, diphtheroids, and *S. viridans*, alone or in various combinations. The blood cultures from 177 cases showed *S. hæmolyticus* alone in 40, *B. coli* in 2, and *S. viridans*, *B. alkalescens*, pneumococcus (Type IV.), and *Staphylococcus aureus* in 1 each. Pus from 44 cases showed *Streptococcus hæmolyticus* alone in 36 and the same organism with staphylococci in 3, with *B. coli* in 1, and with both *B. coli* and *S. viridans* in 1. Of the 3 remaining, 2 showed staphylococci only and the other *B. fæcalis alkaligenes*.

Thus, 76 per cent. of cases showed *S. hæmolyticus* in the uterus; 22·9 per cent. showed it in the blood, and of those with secondary suppurative processes 93·4 per cent. showed it in the pus. Of the 46 cases with a fatal issue, 34 were infected with the hæmolytic streptococcus and 11 had sterile blood cultures; but of the latter, 6 yielded the organism post mortem. In 43 out of the 46 cases it was obtained from one source or another.

Of 24 cases of septic abortion, 4 died; the uterine cultures in 11 cases showed *S. hæmolyticus* alone, in 3 more the same organism with others, and various other organisms in 11.

There can, therefore, be no doubt in the present series of the rôle played by *S. hæmolyticus*.

SOURCE OF THE ORGANISM.

Apart from the work of J. Nixon and H. D. Wright,[2] no effort seems to have been made to trace the source of infecting organisms in sporadic cases by modern bacteriological and immunological methods. In this investigation, as soon as *S. hæmolyticus* was found in a uterine culture, the various secretions and mucous membranes of the patient were examined, and throat and nose swabs were obtained from any persons who had been present at the confinement. When the uterine solution showed *B. coli*, specimens were obtained from the patient, but not from the attendants. The materials were cultured directly on sheep's-blood agar plates and in sheep's-blood broth. If the initial plates did not show the organism after incubation at 37° C. for 24 hours, the blood-broth cultures were also plated on blood-agar. The strains were then examined for their hæmolytic activity and their action in carbohydrate media. To prepare agglutin ing sera numerous rabbits were immunised with kille strains of *S. hæmolyticus* and *B. coli*. Compl serological identification of the strains was established.

The report gives details of the examination in each of 21 cases, 18 of them being puerperal fever and 3 being septic abortion. The cultural characteristics of all strains of *S. hæmolyticus* were fully investigated and the results are given in a table. The majority gave the typical fermentation reaction—viz., acid in media containing saccharose, lactose and salicin, and no acid in media containing mannite inulin and raffinose. Four strains from two sources produced no acid in lactose but were otherwis similar to the rest in their sugar reactions. The coliform strains showed considerable variation in their action on saccharose, but otherwise were much alike in that they produced acid in lactose, salicin and dulcite, and no change in adonite. In litmus milk they produced acid and clot, and they liquefied gelatin. They failed to grow in Koser's medium, produced indol but no methyl-carbinol, and in only one instance failed to give a positive methyl-re reaction. The cultural characteristics of the strains were, therefore, of only slight value in indicatin

[1] Causation and Source of Infection in Puerperal Fever. By J. Smith, M.D., D.Sc., M.R.C.P., D.P.H., Department of Health for Scotland, Edinburgh. H.M. Stationery Office. 1931. Pp. 54. 1s.

[2] THE LANCET, 1929, i., 1242.

the common source of their origin. A study was undertaken to determine the incidence of the various serological types, and the results showed very diverse strains of *S. hæmolyticus* and of *B. coli*. The results are summarised in the above table.

Thus, in a group of 18 cases infected with *S. hæmolyticus*, the source of infection was determined in 15, of which 13 were cases of puerperal fever and 2 were cases of abortion. Of the former the strains were found to come from an extrinsic source in 12, and in every case but one that source was the throat or nose of the doctor, student, or nurse in attendance. In only 1 case could the infection be regarded as autogenous, and this patient was suffering from a streptococcal infection of the hand. In the 2 cases of abortion the source was extrinsic in one and intrinsic in the other, the organism being found in the doctor's throat in one case and in the patient's fæces in the other. Of the three cases of *B. coli* infection, two were puerperal fever and one an abortion with *B. coli* septicæmia. In one case of puerperal fever the organism was also found in the urine, and the other case it was found in the fæces.

Importance of Carriers.

This investigation, therefore, again points to a arrier as the source of puerperal infection, the carrier being usually free from any gross signs. The impression left is that the majority of cases are produced by he physician or nurse actually introducing the treptococcus in the course of examination or manipuation. In all the 21 cases of puerperal sepsis the æces and urine were examined, and in not one was a hæmolytic streptococcus found. Throat and nose wabs from one patient, nine doctors, and five nurses howed the organism.

The problem of prophylaxis is therefore the problem f the carrier, about whom little is known at present. nfection could, at any rate, be prevented if doctors, midwives, and nurses took appropriate precautions, uch as the wider use of masks and the more effective ntiseptic ritual for the hands recommended in the ecent Interim Maternal Mortality Report of the Ministry of Health, 1930. The patient herself should e examined for septic foci and material should be ubmitted to bacteriological examination, and if the octor has any significant septic foci he should also ubmit material. Infection by *B. coli* and other fæcal ypes seems likely to be carried up the vaginal canal y examination. H. W. Mayes has suggested erilisation of the thighs, perineum, and vulva, gether with the introduction of 4 c.cm. of 4 per nt. mercurochrome 220 soluble into the vagina. his report suggests that maternity beds in hospitals hould be isolated by metal or glass screens, and hat no patient should be examined or treated in he common ward. Labour and treatment should be onducted with modern aseptic surgical technique, cluding adequate masking.

MEDICINE AND THE LAW.

Burns from Hot-water Bottle: Unsuccessful Action against Surgeon and Anæsthetist.

In the latest attempt to hold an operating surgeon able for injuries unfortunately caused to the patient y burns from a hot-water bottle, there was a chance hat Mr. Justice McCardie would pronounce some uthoritative ruling on the legal position which would ave given valuable protection to practitioners in milar circumstances in the future. The case, however, was settled before the defence was opened. It had become clear that the operating surgeon and anæsthetist could not possibly be held negligent, but this satisfactory result is only half the battle so long as practitioners can be dragged into the law-courts at great expense of time and money to defend themselves against allegations of negligence which ought not to succeed. In the recent case the proprietress of the nursing-home had admitted liability and had paid £600 into court—though of this latter fact the jury would be unaware. The surgeon and anæsthetist strongly denied negligence and the surgeon counter-claimed for £200 for professional fees. Under the terms of settlement the plaintiff took out the £600 in satisfaction of her claim for damages and an agreed sum for her costs was endorsed on counsel's briefs. She abandoned her action against the surgeon and anæsthetist, who were consequently awarded costs; it is understood that this award will not be enforced and that the counter-claim for fees, though successful, will also be forgone out of sympathy for the plaintiff's most regrettable injury. In announcing the settlement, Mr. Norman Birkett, K.C., made it clear that there never had been any complaint of the two practitioners' skill, care, and judgment. The allegation of negligence against them was based on their supposed duty to prevent such an accident as occurred. The facts and the answers of the plaintiff's own witnesses in cross-examination had made Mr. Birkett's allegation difficult to prove. A rubber hot-water bottle had been used to warm the operating-table in a nursing-home in North Wales. During the operation a nurse gave the bottle to a maidservant with instructions to fill it and place it in the patient's bed where there were already two stone hot-water bottles. After the operation the patient was carried to her bedroom on a stretcher; before she was moved from stretcher to bed, the two stone bottles were taken away but it was not perceived that the rubber bottle was in the bed beneath a mackintosh sheet and a draw sheet. The resultant burning (at the end of the spine and across the buttocks) was very serious; 18 months later the burn was not completely healed, and there remains a likelihood of permanent disability. In cross-examination, the nurse (a witness called by the plaintiff) agreed that it was the nurse's duty to look after hot-water bottles and to prevent patients from burning; she had never known an operating surgeon take part in filling hot-water bottles; if the surgeon did such a thing, she would regard it as an interference with the nurse's duties. As regards the anæsthetist's responsibility, the nurse agreed that the eyes of the anæsthetist must, like those of the surgeon, be always on the patient. When the rubber bottle was given to the maidservant, said the nurse, both surgeon and anæsthetist were fully engaged in attending to the patient. These answers, naturally, though they emphasised the importance of great care in the training of nurses, did little to assist the plaintiff's case against the two practitioners.

It is possible that some day the medical profession may undertake some collective system of insurance against patients' injuries whether or not the injuries are caused by circumstances over which the practitioner has control. The prospect is unlikely, though the legal profession (under conditions which are not wholly parallel) seems ready to consider some plan of fidelity guarantee by which solicitors as a whole will insure an individual client against the frauds of an individual solicitor; indeed in New Zealand contribution to an indemnity fund for compensating defauded clients is already obligatory upon all legal practitioners. Meanwhile, it seems scarcely fair that surgeons and anæsthetists should be the target of charges of vicarious negligence in hot-water bottle cases largely because the plaintiff's action against maidservant, nurse, or nursing-home is not likely to yield substantial damages in hard cash. Parliament would be asked in vain to find time to pass even a one-clause Surgeons' and Anæsthetists' Protection Bill to limit liability for other people's unfortunate oversights. The only remaining hope is that our judges will some day take judicial cognisance of the routine of the operating-theatre and will promote procedure by which actions against surgeon or anæsthetist in such circumstances as we have described may be struck out at the earliest possible moment. Reading between the lines of the report of the case under discussion, one may reasonably assume that the judge brought strong pressure to bear upon the parties in the successful endeavour to obtain a settlement. The action was one in which the plaintiff's misfortune was sure of popular sympathy; it was the more necessary to see that the defendants' rights were not prejudiced on that account. Plaintiff's counsel, in announcing the settlement, admitted that he could not substantiate the charge of negligence against surgeon and anæsthetist. This means that, if the case had proceeded to a finish, the two practitioners must have been awarded costs, the counterclaim for fees must have succeeded with costs, and the judge would presumably have given the jury a direction on the non-liability of the practitioners which would have been important for future reference. Instead of this result, the counterclaim for fees (part of which must have represented out-of-pocket expenses) and the awards of costs are nullified by an agreement not to enforce them. It is good that all charges of negligence against surgeon and anæsthetist are frankly and fully withdrawn; it is clear that the withdrawal is not part of a compromise on the issue of negligence. Everyone will admire the generous forbearance of the two practitioners, but many will regret two features of the case—first that, in the benevolent atmosphere created by the judge's intervention, a settlement was partly purchased out of the pockets of innocent parties who were entitled to be indemnified, and secondly that the outstanding point of principle for which the two practitioners stood was not recorded in a judicial ruling.

The Jury of Matrons.

If (as happened the other day) a pregnant woman is sentenced to death, she is entitled to plead pregnancy. If the fact of pregnancy is established, she is entitled to be reprieved—not for her own sake but for the sake of the child which may be born. For the purpose of determining whether the woman is pregnant or not, there must be an inquiry by a panel of 12 matrons (or "discreet women") chosen from the women present in court. The procedure is of
but of the latter uity. The Commissioners who were
In 43 out of the ft a criminal code 50 years ago

ed between the state
and is "barely with

child" and that of the woman who has conceived "with quick child," as though the old idea were true that the fœtus is not alive until the woman "quickens." Since in any case the jury of matrons would not nowadays be allowed to come to a decision without the assistance of medical evidence, it is the more desirable that the question of the prisoner's pregnancy should be decided directly by medical testimony instead of being referred to a tribunal which is a curious survival of times when medical knowledge was neither far advanced nor easily available. It may be added that the decision of a jury of matrons is also obtainable in civil cases when there is a risk of imposture in matters of legitimacy and to prevent frauds through suppositious children. In civil cases, however, the idea of requiring the services of 12 matrons or discreet women is even less justifiable than in criminal proceedings where there is at any rate some analogy with the theoretic protection of trial by a jury of one's peers.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

DEFICIENCY DISEASE.

MUCH vague ill-health amongst the poorer population in India is due to diet which is deficient in one o more vital elements, and it is probable that many actual outbreaks of deficiency diseases pass unnoticed. Beri-beri in particular must occur fairly frequently, if the facts were known. Some cases have recently come to light in the house of a medical practitioner in Noakhali district. Of 14 inmates 8 were attacked, a child of 18 months, who was living on milk, and five others who only took food occasionally in the house, escaping. A similar outbreak occurred in the house of a neighbouring cultivator. In this, out of 12 inmates, all but one, also a child living on milk, were attacked. The cause is stated to have been the use as a staple diet of milled rice, which was stor in the dark on a damp mud floor. Dr. Margare Balfour, who has been investigating infantile mortality in Bombay, has drawn attention[1] to another possibl manifestation of the results of deficient diet. Sh has come to the conclusion that prematurity is mor frequent in India than in England, and thinks tha it may be an important factor in the higher infan mortality. A remark in the report of the healt officer of Bombay is quoted to the effect that debilit and prematurity play a great part in the excessi number of deaths in the first four weeks of life. A investigation of the diets of women of differen classes in Bombay by Wills showed that the food the women of the hospital class who had give birth to premature children was deficient in vitamin A, B, and C, with a specially marked deficiency in The diet of these women consisted chiefly of polishe rice and white bread. Miss Balfour suggests that deficiency may lead either to weakness of the ger cells, a failure of the growth impulse of the fœtus, premature thinning and separation of the decid membrane.

THE CLEARING OF JUNGLE TRACTS.

There is a very old belief that tropical forests always associated with malaria, and that the cleari of jungle tracts is the first step in their improvemen from a sanitary point of view. Mr. M. O. T. Iyeng

---

¹ Causation and Source of Inf
By J. Smith, M.D., D.Sc., M.R.C.
Health for Scotland, Edinburgh. H
Pp. 54. 1s.

[1] Indian Medical Gazette, November, 1930.

entomologist to the Public Health Department of Bengal, in a recent paper, examines this question, and comes to the conclusion that, in Bengal at least, primitive jungle—i.e., uninhabited land covered with orest trees, shrubs or brushwood tall and thick nough to produce shade, and prevent much exposure f the ground to sunlight—is more free from malaria han are adjacent clearings. He points out that ungle anophelines, which breed and live inside the orest, and normally feed on wild animals, have rdinarily very poor chances of getting an effective eed of malaria, and the prospect of transmission to uman beings is remote. Moreover the species most frequently found within the uncleared jungle re not carriers, whereas directly clearings are made . *ludlowi* and other notorious carriers appear. It eems to be a fact that the bad reputation of jungle r malaria is due more to clearings and their human habitants than to the primitive conditions. One the tragedies of tropical sanitation in the past has een the expenditure of large sums of money in earing forest areas, with the idea that the public lth would thereby be improved. In the Sunder- s, where Mr. Iyengar conducted part of his searches, the forest officials often live in small useboats, anchored in creeks and channels, and found that the best way to protect himself against alaria was to take his boat before sunset into the ncleared jungle area, and spend the night there.

A CASE OF POISONING.

The Indian medical jurist often has curious problems unravel, and they are not made simpler by the evalence of poisonous reptiles. It is generally lieved that a large proportion of the many thousands deaths which are returned annually under the ad of snake-bite are really due to homicidal isoning, or other crime, which can seldom be ought home in the country districts, owing to the actice of cremation and other reasons. An account the *Times of India* (Mail Edition) of Dec. 13th, 30, runs:—

> "An extraordinary case of poisoning in which 45 rsons have lost their lives is reported from Erode. The ctims of this terrible tragedy were students residing in e hostel of the London Mission High School at Erode d a cook. They took their midday meal as usual recently, t shortly after died one after the other in spite of medical l. The hostel cook who prepared the meal also died as a sult of eating it. A poisonous reptile (called *aranai* in mil), which is stated to have been found in the soup rved to students, is believed to have been the cause of eir deaths. There is a saying in Tamil that the bite of *aranai* means instant death."

do not know what *aranai* stands for but, so far I am aware, snake poison, when taken by the outh, is decomposed on entering the stomach, and s no poisonous effect, while lizards are innocuous. hat was the sequel of this fatality is not reported, t presumably it would be a case for police inquiry.

THE INDIAN STUDENT.

The undergraduate of Indian descent comes in for ood deal of criticism, which is sometimes of a rather friendly nature. He is far removed from the average glish student in many of his most prominent aracteristics, and it is therefore hardly fair to judge m by the same standards, apart from those arbi- trily set in examinations, where he is well qualified hold his own. One of his most obvious traits is a ndency to the abstract rather than the concrete. om the medical standpoint one would expect him make a better physician than surgeon, and this think is usually true. Treves once said that every edical student ought to have a course of carpentry. If this applies in England it is still more necessary in India. An English student at all events comes to the dissecting room having learnt in childhood to avoid striking his thumb with a hammer, and with some knowledge of a knife and fork. A high-caste Hindu has had neither of these preliminary advantages, and it is to his credit that he sometimes does well at games. That he has many other good qualities is testified to by Sir Ross Barker, in his convocation address at the Agra University. From a very extensive acquaintance Sir Ross said that he was a profound believer in the qualities, both mental and moral, of the Indian undergraduates of the present day. He spoke of their industry, grit, and perseverance, shown often amidst great difficulties and obstacles, and said that he admired especially their good temper and philosophical demeanour under adversity.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

PRECAUTIONS AGAINST INFLUENZA.

The Secretary of the Department of Local Government and Public Health has addressed to all public health authorities in the Free State a letter advising the adoption of protective and preventive measures against influenza. He points out that, while there is neither a heavy enough incidence of influenza nor a heavy enough mortality to give rise to immediate anxiety, yet plans should be ready for dealing with any threatened outbreak, for the disease has recently occurred in several parts of the country. Sanitary authorities are recommended, in conjunction with their medical officers of health, to formulate schemes for the coördination of all medical, nursing, and public health services in their districts. In particular, provision should be made for medical assistance, including nursing, for patients suffering from pneumonia, whether due to influenza or not. Hospital accommodation should be in readiness for the treatment of sudden or severe cases of influenza. The sanitary authority might consider the question of enlightening the public, by means of leaflets and posters, in regard to the measures to be adopted for personal protection. It is suggested that endeavours should be made to establish a voluntary system of notification of influenza, which is not at present on the list of diseases compulsorily notifiable. Attention is drawn to the serious pulmonary, renal, and nervous complications and sequlæ which may be associated with even a mild attack. Advice is given about the avoidance of overcrowding in public assemblies, the propriety of closing schools during the prevalence of an epidemic, and the social self-isolation of infected households. Warning is given of the special danger of indiscriminate spitting.

HOSPITAL CHARGES TO INSURANCE COMPANIES.—The Yorkshire voluntary hospitals committee has decided that the payment made by insurance companies in respect of motor accident cases should be not less than 11*s.* 6*d.* per day.

HONOUR TO A MEDICAL MAN.—The Bangor city council have conferred upon Dr. Griffith Evans, Bangor, the honorary freedom of the city in recognition of the distinguished services rendered by him to the cause of science. Dr. Evans is 96 years of age. His work as a medical man and veterinary surgeon in India and in the United States had reference to the discovery of the trypanosome, the investigation of an infection among army horses in India, which he found was due to anthrax, and in 1880 the cause of "surra," a disease very fatal to horses and camels in the Indian Army.

CORRESPONDENCE

A SUGGESTED CAUSE OF NEPHROSIS.

To the Editor of THE LANCET.

SIR,—After reading the lecture upon nephrosis by Dr. T. Izod Bennett, published in your issue of Jan. 17th (p. 115), I beg to offer the suggestion that some of these conditions of nephrosis may be purely bacterial in origin. During the war in the trenches one saw cases of nephritis which developed suddenly, with no symptoms except œdema of the face and feet, and a feeling of lassitude. These cases went at once to hospital and one saw them no more. During 1917–18 when in charge of a war hospital at home, I had cases admitted with similar symptoms to those which I had noticed in the trenches. Amongst some 1400 odd patients admitted from January, 1917, to November, 1918, I had 16 such cases under my care, with œdema of the face and feet, albumin in the urine, and, microscopically, leucocytes, hyaline and granular tube-casts, and cocci. No complaints, beyond feeling tired and slack, were made, and no blood pressure was over 140 mm. Hg.

The urine was examined as follows. Immediately after being passed into a sterile flask, 20 c.cm. was centrifuged in sterile glasses, the supernatant fluid was poured off, and the residue distributed between two large sloped agar tubes, and incubated. In every case many colonies of cocci grew, never less than ten colonies, frequently more. These colonies resembled *Staphylococcus aureus*, but when placed in normal saline to make a vaccine these organisms did not make a uniform emulsion, such as *Staphylococcus aureus* does, but required beads to break them up. I regret that no further bacteriological examinations were made with these cocci, owing to the pressure of work. The vaccine, autogenous in every case, given in very small doses to begin with, proved most satisfactory. In every case the œdema cleared up, and the bacilluria and albumin disappeared. The only other treatment adopted was rest in bed, and a dietary largely composed of milk, which was so unpopular that it was rarely persisted in for more than a week. These 16 cases were all discharged within two months of admission and I lost sight of them.

At the end of November, 1918, a nursing sister who had served in France since 1914 was invalided out of the service, as a case of chronic nephritis. She had been in hospital for three months under treatment, and her œdema had disappeared, but when I saw her she felt unfit and lacking in energy, and as she was warned that she would not be able to follow her vocation of nursing she was naturally depressed. The urine in her case was drawn off by catheter. It contained a large quantity of albumin, while hyaline and granular tube-casts, many leucocytes, and a few cocci were seen on microscopic examination. Her blood pressure was round 130 mm. Hg. The patient was treated with an autogenous vaccine, and within six weeks the symptoms had cleared up. She is to-day in active practice as a nurse and has had no return of the nephritis. About the same time that I saw the nurse I was asked by a colleague to examine a specimen of urine microscopically. The patient, a man of about 50 years of age, of great physical and mental ability, had developed nephritis, and the prognosis given him was not hopeful. The urine showed a fairly acute condition, because, in addition to the symptoms in the previous cases, a few red blood corpuscles were present. The cocci in this case I believed to be *Staphylococcus aureus*: I suggested trying an autogenous vaccine, which was done with good results. The condition cleared up in two months and the patient is as fit to-day as he was previous to the attack of nephritis.

Since these cases passed through my hands I have had during the past 12 years seven cases of œdema with albumin, leucocytes, tube-casts, and bacilli in the urine. There were no symptoms except œdema, and no symptoms of arterial tension except in one case. The bacteriological findings in these seven cases were as follows:

Streptococci and colon bacillus ..	1 case.
Staphylococcus aureus	3 cases.
Colon bacillus	2 "
Micrococcus tetragenus	1 case.

All these cases under autogenous vaccine treatme cleared up, except the case with tetragenous infecti The patient is a man of 65 years of age, his arte tension is 200 mm. Hg, and his arteries atheromatous.

My only excuse for recording these cases is the that so far as I have read no one has suggested these cases of nephrosis may be of bacterial origin.

I am, Sir, yours faithfully,

Murthly, Perthshire, Jan. 19th, 1931. L. C. BRUCE.

HÆMATEMESIS AS A SYMPTOM OF PEPTIC ULCER.

To the Editor of THE LANCET.

SIR,—Writing in THE LANCET of Dec. 20th, 1 (p. 1346), Mr. Basil Hughes remarks that in 25 experience he can recall only two cases of true rhage from a gastric or duodenal ulcer. He goes to say:—

> "Such experience shakes one's faith in hæmatemesis trustworthy symptom of gastric or duodenal ulcer, text-books still proclaim it and students are still taught If it is a symptom, it is a very rare symptom; such my surgical and post-mortem findings."

As it seemed that such a statement might misleading to the medical student, the records of of gastric ulcer treated in the wards of St. Thom Hospital during the year 1929 were consulted. T evidence available apparently vindicates the tex books. A total of 184 cases were classified as gast ulcers; 20 cases were regarded as "non-prove in the absence of barium meal examinations; in other cases the diagnosis was made on the &c., and on the presence of suspicious X ray such as pyloric spasm and local tenderness manipulation. In the remaining 139 cases diagnosis was considered to be beyond cavil on following evidence:—

(1) 105 cases were verified either by the presence of definite Haudek crater on barium meal examination, or the finding of an ulcer on operation.

(2) 21 cases were operated on for perforated ulcer (3 di

(3) 13 cases were verified at autopsy.

Now of these 139 cases a history of hæmatem was obtained in 42—i.e., an incidence of 30 per at least, leaving out a good many suggestive unproved cases. Of the cases examined at au eight had died as a direct result of hæmatemesis 6 per cent. of the proved cases. In seven of these eroded artery was easily demonstrated at the or in the wall, of the ulcer. The remaining showed a lesser curve ulcer with no bleeding po but immediately opposite, on the greater curve, was a circular area of acute hæmorrhagic gastritis.

It is always risky to argue from statistics or from personal experience, but these figures seem to indicate that it is still legitimate to proclaim hæmatemesis as one of the most trustworthy symptoms of gastric ulcer. I am, Sir, yours faithfully,

THOMAS MORTON,
Medical Registrar, St. Thomas's Hospital.
Jan. 20th, 1931.

INSULIN PHOSPHOTUNGSTATE.

To the Editor of THE LANCET.

SIR,—It was with much interest and great admiraion of the energy of Dr. R. D. Lawrence that I read iis note in your last issue (p. 184). A month or two go I referred to the fact that I was making observaions on this substance and that any way its use for ny lengthy period could not be advocated until vidence was forthcoming that it was innocuous. his cannot be determined for some time. If the hosphotungstate of insulin proves beneficial in abetes (I am not in a position to make any assertion the moment) I should expect its effect to be quite ifferent to that of a soluble salt injected under the kin, because I imagine that its action would be due the insoluble salt being passed through the intestinal all, undergoing decomposition in the tissues and hus liberating insulin. The latent period would be onsiderable. Again the exact nature of the preparaon may have an effect. If dried phosphotungstate e given in suspension it may not have the same ffect as the salt which has not been dried. This ct may be illustrated; I found that if the tannate insulin prepared by adding tannic acid and buffer lts to a solution of insulin hydrochloride were ijected subcutaneously there was only a slight elay in its action, whilst Dr. Hagedorn told me that e prepared and dried tannate of insulin which though containing active insulin did not lower e sugar in the blood of animals which were injected ith a suspension.

I have every confidence in the accuracy of Dr. awrence's observations, but cannot accept his ghtning conclusions as proven.

I am, Sir, yours faithfully,

Monks Corner, Marlow, Jan. 24th, 1931. O. LEYTON.

To the Editor of THE LANCET.

SIR,—It is quite hopeless to expect any internal sulin ever to produce acute hypoglycæmia, or to ppose that insulin and hypoglycæmia are inevitably ked. It is not the insulin itself, but its sudden plication by subcutaneous injection, that produces ute hypoglycæmia. Even then hypoglycæmia can prevented either by previous tying of arms and gs (Bürger and Kramer), or by making the injection ry slowly, drop by drop. Insulin produces hypoycæmia only where it gets a chance of operating the muscular glycogen. This chance is handicapped hen the injection is made intravenously and still ore when insulin is given by mouth. In this case first reaches the hepatic glycogen (Collazo and ubino).

In order to demonstrate the influence of insulin ken internally on the concentration of the bloodgar special precautions must be taken. The nount of the hepatic glycogen must first be minished, otherwise its virtual hypoglycæmic wer will be masked by the glycogen mobilised in e liver. For this purpose H. N. Mukherjee has recommended making the diabetic fast completely for at least 16 and the rabbit even for 24 hours before giving them insulin by mouth. Dr. Lawrence does not make it clear if this precaution was observed or not. The precaution is indispensable only for the demonstration of acute hypoglycæmia, not of the antidiabetic effect of insulin taken internally. This effect is characterised by a slow but steady increase of the patient's tolerance for carbohydrates within the first ten days of regular treatment with internal insulin, as has been pointed out before (see THE LANCET, 1928, i., 159).

I am, Sir, yours faithfully,

Saarbruecken, Jan. 25th, 1931. F. W. FORNET, M.D.

ACUTE TOXIC HEPATITIS AFTER ACRIFLAVINE.

To the Editor of THE LANCET.

SIR,—A large number of drugs are known to be capable of causing liver damage, and Dr. Cullinan in your last issue has called attention to the possible danger in this respect of acriflavine. This has long been used as an external antiseptic, and has also been given by mouth without harmful effects. More recently it has been administered by intravenous injection in the treatment of gonorrhœa. In a series of 100 cases of gonorrhœa treated by intravenous injection of 10 c.cm. of 1 per cent. acriflavine three times weekly three cases of jaundice occurred. The average amount of acriflavine given was 0·78 g. The average time of onset of jaundice was 112 days after the last injection, and its average duration 46 days. In all cases jaundice was well marked and was catarrhal in type with enlargement of the liver and, in one case, of the spleen also. Constitutional symptoms were severe. The effect of the acriflavine on the urethritis will be described at a later date. Yellowness of the skin may occur very soon after the intravenous injection of acriflavine, but this is transient and not due to hyperbilirubinæmia, since the quantitative van den Bergh reaction is normal. It should be noted that the icterus index as a test for latent jaundice is fallacious in these cases.

I am, Sir, yours faithfully,

C. ALLAN BIRCH,
Medical Registrar, Liverpool Royal Infirmary.
Jan. 24th, 1931.

To the Editor of THE LANCET.

SIR,—Dr. E. R. Cullinan's letter raises two issues.

(1) Is acriflavine taken orally "justifiable" in the treatment of gonococcal urethritis? My own observation during five years' use of acriflavine tablets gr. ½, administered orally three or four times a day, for that condition, gives the answer—yes.

(2) Is acriflavine taken orally "unjustifiable" by reason of the appreciable risk of its causing toxic jaundice? During the last five years over 2500 of my male patients suffering from urethritis, in the majority of whom the gonococcus was demonstrated, have taken by mouth for periods varying from two weeks to five months, continuously, an acriflavine tablet gr. ½ three to four times a day. In all of them the drug was absorbed—as the colour of the urine clearly showed. (In fact, over 100,000 tablets have been issued to these patients.) One man, only, after eight weeks on acriflavine gr. ½ t.i.d. per os developed slight jaundice four weeks after ceasing to take the acriflavine tablets. This jaundice disappeared after one week's out-patient treatment by mild laxatives.

Six men only complained of nausea which ceased on discontinuing the acriflavine by mouth.

I therefore submit that within the above-stated therapeutical limits the danger of toxic hepatitis from acriflavine per os is negligible.

I am, Sir, yours faithfully,

H. M. HANSCHELL,
M.O. in Charge, V.D. Clinic, Seamen's Hospital,
Jan. 27th, 1931. Royal Albert Dock, E.

PASTEURISATION OF MILK.

To the Editor of THE LANCET.

SIR,—The ideal "safe milk" is free from pathogenic organisms and retains its nutritional values. It can be obtained from healthy tubercle-free cattle and is drawn under hygienic conditions and protected from contamination in transport from the source to the consumer. Mr. T. B. Macaulay has proved that this can be done on a small scale; at his experimental farm near Montreal, Canada, there is a herd of Friesian cattle; each animal is tuberculin-tested at regular intervals, and for the seventh year in succession the tests have been negative; procedures are adopted for ensuring the purity of the milk, these having proved successful in reducing the bacterial content considerably. The Federal Government of Canada offered free tuberculin-testing to live stock owners in 1897, and plans for eradicating tuberculosis in cattle have been evolved as the result of experience during the succeeding years. It is estimated that the average proportion of tubercle in cattle is less than 5 per cent. at the present time.

The incidence of tuberculosis in cattle in England is estimated at a much higher figure and there is evidence of a large amount of infection in pooled raw market milk. Dr. R. Marguerite Price, bacteriologist to Toronto University, in her studies on "Bovine Tuberculosis and its Relation to Infection in Children" in the Toronto area, has come to the conclusion that pasteurisation of, or boiling, milk prevents bovine tuberculosis in children, and Dr. Harold Parsons produces clinical evidence in support of this conclusion. Statistical evidence in favour of pasteurisation has been produced by Dr. Shirley Wynne, commissioner of health for New York, and the health officers of other large American cities. The question therefore arises, in view of the large amount of bovine infection in this country, should pasteurisation be adopted generally?

In Canada and U.S.A. the generally accepted opinion appears to be that pasteurisation does not materially impair the nutritional properties of the milk. There is evidence, however, that heating milk reduces the amount of vitamin D and available calcium; it also destroys certain organisms which may aid digestion in infancy. As milk is an essential article of diet in infants and young children and as there is a possibility of pasteurisation impairing the nutritional qualities, would it not be safer to give Certified or Grade A (T.T.) milk to infants and young children and reserve pasteurised milk for older children and adults?

Should not pasteurisation of milk even for these individuals be regarded as a temporary expedient only and efforts be directed towards obtaining a general supply of milk free from pathogenic organisms with its nutritional qualities unimpaired?

I am, Sir, yours faithfully,

HAROLD VALLOW,
Tuberculosis Officer, City of Bradford
Jan. 22nd, 1931. Anti-tuberculosis Centre.

MYOMECTOMY.

To the Editor of THE LANCET.

SIR,—I read with much pleasure the leading article in your last week's issue commenting upon my Hunterian Lecture, and beg to answer the pertinent questions.

Of the 30 women who conceived after myomectomy the tumours removed were single in 13 cases and multiple in 17 cases. The numbers of the fibroids removed from the members of the last group were respectively: 32, 29, 21, 14, 14, 11, 10, 9, 8, 7, 7, 5, 5, 5, 4, 3, and 3. I cannot with exactitude give the positions occupied by the tumours as I have no records, but the vast bulk of them were interstitial. Neither can I say how often the uterine cavity was opened, as I do it so commonly. It certainly was opened in all the cases in which the number of fibroids removed was considerable. As regards the "hood" operation. The uterus when refashioned in this way more nearly approximates to the appearance of the normal organ than by any other method. All patients on whom I have performed it have d well, and two of them are amongst the group subsequently bore children. The labours in bo cases were natural.

My thesis was not that myomectomy shou supersede hysterectomy in the treatment of fibroids but rather that it should be the "operation of inclina-tion" in all cases, and the operation of choice i a considerable number.

I am, Sir, yours faithfully,

Devonshire-place, W., Jan. 27th. VICTOR BONNEY.

LEAKAGE FROM OXYGEN CYLINDERS.

To the Editor of THE LANCET.

SIR,—I agree with Dr. Roffey that oxygen cylinde should be tested before issue by chemists, and believe this is commonly done either by testi weight or pressure. I find a more common is that oxygen is lost by leakage in the patient house; the valves at present in use are ofte stiff that it is almost impossible to turn them completely between administrations, unless happens to be a strong male relative avail. Also when turned on, it is sometimes difficult prevent a sudden rush of oxygen, the noise of w most disturbing to a seriously ill patient. It s not be difficult to devise a valve that could be operated. Of course the change over to e acting valves would involve expense to the ma but it would be a boon to patients and those who called upon to use the apparatus.

I am, Sir, yours faithfully,

Tunbridge Wells, Jan. 25th, 1931. R. D. AYLWARD

MOTIVES AND MECHANISMS OF THE M

To the Editor of THE LANCET.

SIR,—If I understand Dr. A. T. Todd's correctly we are to abandon modern psychop because it is libidinous and ridiculous. Appar the fact that it may contain the elements of tr of no consequence. If Truth be unpleasant apparently ludicrous it must be suppressed at all.

All great discoveries arouse both abuse and ridi. The lay public rocked with delight at the idea evolution. The bacterial theory of disease regarded as disgusting.

Because patients are given explanations

requently cure them) instead of bottles of medicine which do not) it is foolish to say that they are not eing treated.

But it seems a great shame that more and more linics for the treatment of early mental disease are pringing up—Dr. Todd could save all this expense ith kaolin, acids and (Ye gods!) raw cabbage.

I am, Sir, yours faithfully,

London, Jan. 27th, 1931. CLIFFORD E. ALLEN.

THE PROBLEM OF REJUVENATION.

To the Editor of THE LANCET.

SIR,—Under this title Dr. Lorand gave an address o the Hunterian Society, an abstract of which appears your columns to-day. His address was a résumé f his experiences at Carlsbad, and its practical lesson as that old age could be considered as a condition f general auto-intoxication, so that the logical way f rejuvenation would lie through dietetic methods —that is, through the stomach and the intestines. In speaking of the consequences of intestinal auto-intoxication he recommended the regular and thorough cleansing of the bowels, saying that one of the best methods was the "entero-cleaner bath." His words, which are quoted in your columns, are not as clear as they might be, and it is my recollection that he added that an apparatus known as the gymnacolon was equally good. I should be glad to know exactly what Dr. Lorand meant by an "entero-cleaner bath." Does the word "bath" refer to a bathing of the intestines or the body. The apparatus he mentioned, the gymnacolon, is for continuous colonic irrigation, the patient lying on a specially constructed chair. Is he referring generally to colonic lavage by an entero-cleaner bath, or is he advocating the repellent technique by which a patient is irrigated while he is lying in a bath? This latter procedure is, in my opinion, most unhygienic, owing to the fact that it is impossible to boil the apparatus between cases, and that there is always a certain amount of leakage into the bath.

I am, Sir, yours faithfully,

Jan. 24th, 1931. V. R.

PUBLIC HEALTH SERVICES

EPORTS OF MEDICAL OFFICERS OF HEALTH.

A Survey of 1929.

DURING the last ten months we have commented n upwards of 100 reports, and it may be of interest summarise the impressions left by their perusal. he year 1929 will be remembered as the worst nfluenza year since 1918. It was also extraordinary s regards weather conditions. Ushered in by fog here was record-breaking cold weather in the first wo months, to be followed by a prolonged drought, nd finally in the last months of the year by a very eavy rainfall with floodings. The rainfall for the hole year was deficient and the hours of bright unshine were above the average. It was, therefore, year of meteorological extremes. It was also a otable year, as preparatory to the great changes nder the Local Government Act, 1929, which came nto force on April 1st, 1930. The various authorities ere preparing their schemes and arranging to put e poor-law institutions to better use. In many ses hospitals were transferred in anticipation. ounty councils were specially considering the organisation of isolation hospitals, while county stricts were looking forward to financial help for ater-supply and sewerage schemes. In the towns forts were being made to secure better coöperation tween the various departments of the public alth service. The effort to avoid overlapping sults in making the work more interesting for the aff. Thus the tendency is to have assistant medical ficers interchangeable between the departments, d nurses who carry out health visitation for all blic health purposes.

GENERAL SANITATION.

Housing.—In a few districts housing shortage was id to be almost overtaken but in many it was still ute. Houses at lower rentals are in demand erywhere, and the reported overcrowding of unicipal houses by sub-letting is one indication. few districts are trying to meet the demand for eaper houses. Portsmouth has adumbrated a heme for slum clearance and the rehousing of the um tenants in municipal houses with abatement the rental in respect of children. Slum clearance s not been attempted except on a small scale. veral reports refer to the need for providing unicipal houses for overcrowded families, undesirble tenants, and families infected with tuberculosis. the metropolitan area the county council estates too far off to benefit the poorer classes in the boroughs who have to live near their work. The L.C.C. allocate half their houses to the borough councils and they make the useful stipulation that every effort should be made to prevent the vacated houses becoming again overcrowded. In some districts—e.g., Kensington—Section 3 of the Housing Act, 1925, which enables the authority to renovate the house in the default of the owner has been found very useful, but in most districts this section was little used. Many county medical officers of health, especially in Scotland, are very enthusiastic about the Housing (Rural Workers) Act, 1926, but on the whole the advantage taken of this Act has been disappointing. There are signs, however, that the new Housing Act of 1930 will be taken in hand more seriously than its predecessors by the local authorities which have to administer it.

As regard *refuse*, experiments have been made in some districts with dustless removal plants. There have been many complaints with regard to the management of tips and the system of controlled tipping has improved matters somewhat.

The prevention of *rivers pollution* is arousing more interest and the establishment of rivers boards meets with more favour. There is more activity with regard to sewage disposal schemes, and efforts are being made by the trades concerned to deal with the nuisances caused by trade wastes. On the other hand, the development of scattered building estates adds to the difficulties of authorities, which have to deal with rivers pollution.

No special progress has been made with *smoke abatement*. Regional committees with statutory powers are difficult to organise owing to local jealousies. Domestic smoke is now definitely recognised as the worst offender in causing atmospheric pollution. Several health authorities have followed the example of Salford in using only smokeless fuel in their offices. Unfortunately very little smokeless fuel is available as yet for would-be consumers.

MILK-SUPPLY.

The misleading nomenclature of graded milks continues to give rise to criticism. There was no evidence of any improvement in England in the percentage of tuberculous milks as the result of recent legislation, but such veterinary inspection as has been inaugurated has not had time to have an effect, and without routine inspection there is little likelihood of early notification of infectious cases by the farmers. The Scottish counties have been more active in providing veterinary inspection, but as a rule it has not been possible to make the inspection at sufficiently short intervals. It is found, however, that veterinary inspection not only improves the sanitary condition of the dairy farms, but leads to economic feeding and milk recording. Several English county medical officers of health advocate more sampling of milk for tubercle by the districts, with a view to the earlier detection of animals giving tuberculous milk. It cannot be said that the follow-up by the county authorities of tuberculous milk reported by outside authorities leads to satisfactory results as the offending cow is only discovered in a small percentage of cases.

INFECTIOUS DISEASES.

The *influenza* epidemic coincided in most places with the severe weather of February. Districts attacked towards the end of February came off better owing to the improved weather in March. The birth-rate was lower than ever and the increased deaths caused by influenza and respiratory diseases resulted in many districts in an excess of deaths over births for the year.

The opinion seems to be growing that there is too much hospitalisation of *scarlet fever*, and that this disease, especially with antitoxin as an adjuvant, might very well be treated at home, thus setting free beds for more serious diseases, such as pneumonia. The duration of the stay of scarlet fever cases in hospital has been much reduced and the use of antitoxin is becoming general.

Diphtheria in most of the districts had a higher case-fatality than in the previous year, and the complaint is widespread that antitoxin in adequate doses is not given early enough. In some isolation hospitals the intravenous administration of antitoxin in very large doses has been efficacious in saving cases admitted in an apparently hopeless condition.

It is becoming customary to immunise scarlet fever cases admitted to hospital against diphtheria and vice versa. Immunisation schemes against diphtheria are not growing rapidly, and a county medical officer suggests that general practitioners should be in a position to offer immunisation to those who desire it.

Most of the cases of *typhoid fever* notified had an untraceable origin whilst a certain proportion were attributed to carriers. The varieties of typhoid nowadays seem to have no preference for the autumn but occur at any time of the year.

Serum for the prevention of *measles* has not come into general use. At the Birmingham City Hospital, when the supply of serum from convalescents had run short, serum from young probationers, who could give a clear history of an attack of measles in childhood, proved a quite satisfactory substitute.

The deaths from *encephalitis* frequently exceeded the notifications owing to the inclusion of the deaths of those who contracted the disease in previous years, when the disease was more prevalent. The provision of institutional accommodation for post-encephalitics is in statu quo, pending the allocation of the ex-poor-law buildings.

SPECIAL SCHEMES.

Maternity and Child Welfare.—Many specially planned centres were opened, sometimes combined with maternity and baby hospitals, and sometimes accommodating all the various clinics. The need for the appointment of obstetricians for antenatal clinics is being better realised, and in some cases consultants have been appointed not only for puerperal fever and pyrexia, but for difficult labours. It is found that the appointment of consultants and the provision of maternity beds leads to more effective notification of puerperal fever.

In the counties the covering of the whole area with a nursing and midwifery service proceeds, but in some cases slowly. Many *orthopædic* schemes have been extended during the year.

A general lack of institutional accommodation for *mental defectives* is reported.

Some of the oil companies are taking an interest in *cancer* research work in Manchester. The experience of Leicester and Willesden appears to indicate that early diagnosis and early operation are more likely to be secured through the persuasive efforts of a municipal centre than by the establishment of an early diagnosis clinic at a general hospital.

Cardiff has been added to the districts which have a hospital and special clinic for the supervision and treatment of early *rheumatic* manifestations in children.

Improved facilities have been provided for the *venereal disease* clinics in several districts. The percentage of default varies much as between one scheme and another (e.g., Edinburgh and Glasgow). The attempt to follow up defaulters has brought out the fact that in a large percentage of cases a wrong address is given. Good results are reported by Portsmouth from the treatment and following-up of congenital cases.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDI

JAN. 17TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 187 (last week 228); scarlet fever, 1768; diphtheria, 1327; enteric fever, 23; pneumonia, 1726; puerperal fever, 70; puerperal pyrexia, 117; cerebro-spinal fever, 29; acute poliomyelitis, 2; acute polio-encephalitis, 2; encephalitis lethargica, 20; dysentery, 15; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 20th–21st was as follows: Small-pox, 225 under treatment, 8 under observation (last week 215 and 3 respectively); scarlet fever, 1585; diphtheria, 1918; enteric fever, 10; measles, 89; whooping-cough, 171; puerperal fever, 30 (plus 12 babies); encephalitis lethargica, 121; poliomyelitis, 1; "other diseases," 91.[1] At St. Margaret's Hospital there were 19 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (1) from enteric fever, 94 (0) from measles, 9 (5) from scarlet fever, 33 (4) from whooping-cough, 39 (8) from diphtheria, 60 (10) from diarrhœa and enteritis under two years, and 146 (27) from influenza. The figures in parentheses are those for London itself.

Thirty-five fatal cases of measles were reported from Liverpool, 10 from Bristol, 8 from Hull, 6 from Nottingham, 5 from Birmingham, and 4 each from Birkenhead, Gateshead, and Newcastle-on-Tyne. Leeds and South Shields each recorded 3 deaths from whooping-cough. Diphtheria claimed 5 victims at Liverpool and 3 at Salford. Diarrhœa was credited with 12 deaths at Liverpool, 7 at Birmingham. The 119 fatal cases of influenza outside London are scattered over 52 great towns; 27 were reported from Liverpool, 7 from Birmingham, and 5 each from Bolton, Manchester, and South Shields.

The number of stillbirths notified during the week was 282 (corresponding to a rate of 42 per 1000 births), including 50 in London.

---

[1] The unusual size of this figure is due to the fact that patients suffering from certain infectious diseases, not admissible under the Public Health London Act, 1891, and which have hitherto been received into the general hospitals of the Council (the former poor-law infirmaries), are now, as a matter of convenience, admitted to the infectious diseases hospitals, as both these classes of hospitals are now administered by the London County Council under the provisions of the Local Government Act, 1929.

SUN BALCONIES AT COSSHAM HOSPITAL.—The Cossham ladies needlework guild has presented to this memorial hospital at Kingswood, Bristol, a series of sun balconies which were opened last week by the Sheriff of Bristol, Mr. H. G. Tanner. The collecting of the cost, £680, occupied the guild for ten years.

OBITUARY

HARRY DE RIEMER MORGAN, M.A. Oxf., M.R.C.S. Eng., D.P.H.

Dr. Morgan, whose death occurred at Aldenham, where he had been living in retirement for the last 20 years, was at one time a member of the council of the Lister Institute, and a keen worker in preventive medicine. After graduating at Oxford in 1887 he took his medical course at St. George's Hospital, qualifying in 1892, and made some voyages on Union line steamships before settling at Cockington, Devon, where he became medical officer of health. Taking the D.P.H. in 1901, he began his work at the Lister Institute, partly in coöperation with Mr. J. E. Barnard, partly with Prof. J. C. G. Ledingham. One of his first studies, published in our own columns, dealt with the presence of bacteria in the organs of healthy animals.

Prof. Ledingham writes: "Morgan's bacillus may possibly be the only link between the younger generation of bacteriologists and the H. de R. Morgan whose death took place at Aldenham on Jan. 15th, but to many of his old associates at the Lister Institute the news of his decease will awaken the kindliest of memories, for to them and his familiars in pre-war days he was known as 'Jimmy' Morgan. During the ten years preceding the war Morgan was a well-known and much esteemed figure in the bacteriological laboratories of the Institute. Except for a tenure of the Ernest Hart memorial scholarship, during which he carried out his investigations on the bacteriology of summer diarrhœa, Morgan was a voluntary worker, but he took his work very seriously and was most conscientious in its performance. Having been actively interested in public health before circumstances made it possible for him to settle down to laboratory work, Morgan applied himself to practical problems. He carried out in 1904 and 1905 investigations on the bacterial content of the tissues of healthy animals, and on the organisms associated with food poisoning so far as the differential criteria applicable at the time permitted. He was particularly concerned with the distribution of the group in the various domestic and laboratory animals. These earlier studies were the prelude to an intensive four years' study (1905–08) of the bacteriology of summer diarrhœa, in the course of which he drew attention to the importance as a possible ætiological agent of the organism first described by him as *Bacillus No. 1*, and which is now known as Morgan's bacillus or in American literature *B. morgani*.

"Morgan himself was extremely cautious in ascribing ætiological importance to his bacillus. Even now there is no conclusive evidence that this organism is ætiologically related to the condition with which it was first associated, or indeed to any specific human disease, but in saying so it has to be admitted that our knowledge of the pathogenesis of many acute intestinal disturbances remains very fragmentary when we exclude from consideration the much studied salmonella and dysentery groups. One hears little of summer diarrhœa now. Explosive outbreaks of toxic diarrhœa would appear in these days to be frequently due to some member of the dysentery group, and particularly the Sonne type. At the period of Morgan's study of summer diarrhœa he took particular pains to search for true dysentery strains in view of American experience, but failed to secure evidence that these came into the picture.

"Though the ætiological importance of Morgan's bacillus remains equivocal, it takes a secure place in systematic bacteriological literature. The last important work by Morgan was his study of various dysentery-like organisms recovered from English sources, mainly typhoid convalescents and suspected typhoid carriers. A certain proportion of these casual strains qualified for admission to the mannite-fermenting dysentery group, and it was inferred that genuine dysenteric infections were probably more common in this country than was then believed. This conclusion was reached before the war, which itself undoubtedly contributed materially to the wider distribution of dysenteric infection in post-war times."

FREDERICK MEADOWS TURNER, M.D. Camb., D.P.H.

Dr. F. M. Turner, who was for 34 years medical superintendent of the South-Eastern Fever Hospital, New Cross, died on Jan. 17th at the age of 64 years. Born at Norwich in 1866, son of the Rev. F. Storrs Turner, he went to the City of London School and took the B.Sc. Lond. before going up to Trinity College, Cambridge, with a scholarship. He graduated in medicine in 1892, continuing as house physician at Guy's Hospital, where he had done his clinical work, and studying also at Heidelberg. In the next year he entered the service of the Metropolitan Asylums Board as assistant to the late Dr. R. A. Birdwood at the North-Eastern Hospital. Promotion came quickly and four years later he was appointed superintendent of the South-Eastern Hospital, a post which, excepting for a brief interval when the hospital was rebuilding, he kept until the time of his death. With first-rate mental equipment he soon became a leading authority on infectious diseases, especially on the statistical side, and his report of 1906 on return cases of scarlet fever has become a classic. About the same time he contributed to *Biometrika* a paper on the correlation between vaccination and small-pox in the London epidemic of 1901–02. It was Turner who showed, in 1922, the rise in mean age of scarlet fever at times of epidemic prevalence. But his scientific interests were not confined to medicine. He studied biology in all its branches, working with Prof. A. E. Boycott on various biological problems, one of these being the inheritance of sinistrality in the snail, communicated to the Royal Society. Dr. J. B. Byles, to whom we are indebted for many of these biographical details, writes:

"Turner was an indefatigable worker devoted to his patients, his staff, and his hospital. He ruled by kindness and was beloved accordingly. His mild reproof was as efficacious as another's anger. He spared no trouble or inconvenience to give help or advice to any who needed it, and his colleagues in the service valued his sound judgment and considered counsel. Turner lived most of his life in the heart of London, but he knew and loved the country and was a delightful companion on a ramble. One of his favourite recreations was sailing, and for years he might be seen dodging the heavy traffic on the swift tides of the lower Thames, even in dirty weather. Some years ago, while sailing on the Norfolk Broads, he suffered a perforation of a duodenal ulcer for which he underwent operation five hours later at the Norfolk and Norwich Hospital. With similar courage he submitted to the severe operation which

(*Continued at foot of next page.*)

at present in a position to answer definitely the questions of the hon. and gallant Member, but I am informed that two of the borough councils have entered into fresh contracts for the tipping of refuse on a new site under improved conditions.

Deaths from Tuberculosis.

Lieut.-Colonel **Fremantle** asked the Minister of Health the number of new cases of and the number of deaths from pulmonary and non-pulmonary tuberculosis notified in 1915, 1920, 1925, and 1929, respectively, and the estimated percentage of such cases attributable to infection of bovine origin.—Mr. **Greenwood** replied: The numbers asked for are shown in the following table:—

ENGLAND AND WALES.

Year.	Pulmonary tuberculosis.		Non-pulmonary tuberculosis.	
	New cases notified.	Deaths.	New cases notified.	Deaths.
1915	68,309	40,803	22,283	13,492
1920	57,844	32,791	15,488	9,754
1925*	60,770	32,382	20,667	8,005
1929*	57,274	31,425	18,682	6,565

* For the years 1925 and 1929 the figures include all new cases coming to the notice of medical officers of health, whether as a result of notification under the Public Health (Tuberculosis) Regulations or otherwise.

I am advised that there is no information available on which to base any reliable estimate of the numbers of these cases or deaths which were due to infection of bovine origin.

FRIDAY, JAN. 23RD.

The Case of Mrs. Olive Wise.

Mr. **McEntee** asked the Home Secretary whether he would consider arranging for the removal of Mrs. Olive Wise, of Walthamstow, from Holloway gaol to some private maternity home during the period of her confinement; whether he would give further sympathetic consideration to her case, with a view to her early release from prison; whether he would give consideration to the present state of the law, with a view to its modification, so that in future any female prisoner who was convicted of murder should not be sentenced to death if it was proved that she was pregnant; and if he would consider whether any amendment of the existing law was necessary to enable judges to assess the responsibility of the man in such cases and to ensure that where such responsibility was proved the woman would not be forced to bear all the punishment.—Mr. **Short** replied: As my hon. friend is aware, that sentence of death in this case has already, on the recommendation of my right hon. friend, been commuted to penal servitude and in due course my right hon. friend will consider very carefully whether, having regard to all the circumstances, he would be justified in recommending further clemency. He is advised that there is no power to order the removal of Mrs. Wise to a private maternity home during the period of her confinement. Proper provision is made in prison for the treatment of such prisoners and for their necessary care. With regard to the third part of the question, I would refer my hon. friend to the reply given yesterday. The last part of the question raises considerations of a far-reaching character with which it is impossible to deal within the limits of an answer to a question, and my right hon. friend will write to my hon. friend on the matter.

Production of Lymph from Rabbits.

Mr. **Freeman** asked the Minister of Health how many rabbits had been used in the preparation and production of vaccine lymph at the Government lymph establishment for each year since rabbits were first used for this purpose; and what was done with them after the experiments had been completed.—Mr. **Greenwood** replied: Between 100 and 200 rabbits are used annually for the purposes indicated in the question. The rabbits are killed as soon as these purposes have been fulfilled.

MONDAY, JAN. 26TH.

Kirkburton Mental Hospital.

Major **Cohen** asked the Minister of Pensions whether there was any possibility of the Kirkburton mental hospital being required by the West Riding authorities; and, if so, whether he would give an assurance that the pensioner patients at present in that hospital would not be returned to county mental institutions, but would be transferred to a Ministry institution where they would receive treatment exactly similar to that now being given at Kirkburton.—Mr. W. **Paling** (Lord of the Treasury), who replied, said: The answer to the first part of the question is in the affirmative. The policy of the Ministry as regards the type of case at present accommodated at Kirkburton remains unaltered and steps will be taken as occasion arises to make such similar arrangements as may be necessary for present and future patients who may be able to benefit by this form of treatment.

TUESDAY, JAN. 27TH.

The Washington Hours Convention.

Mr. **Graham White** asked the Prime Minister if it was the intention of the Government to proceed with the Bill to ratify the Washington Hours Convention. Mr. **Snowden** (Chancellor of the Exchequer) replied: The Government wish to proceed with the Hours of Industrial Employment Bill, but my right hon. friend cannot say when the further stages of the Bill will be taken.

New Factory Legislation.

Mr. **Charles Williams** asked the Prime Minister on what day he proposed to introduce legislation to amend the Factory Acts.—Mr. **Snowden** replied: My right hon. friend regrets that he cannot make any further statement on this subject.

Russian Timber and Public Health.

Sir **William Davison** asked the Minister of Health whether instructions had been, or would be, given to officials of the Ministry at the ports concerned to inspect all imports into this country of Russian timber, including doors ready to be placed in houses, produced under insanitary conditions, in order to avoid danger to the public health by reason of insects bred in such conditions being imported with the timber.—Miss **Lawrence** (Parliamentary Secretary to the Ministry of Health) replied: The answer is in the negative. My right hon. friend is advised that there is no reason to apprehend danger to the public health from the importation of this timber.

Cost of Poor-law Infirmaries.

Dr. **Hastings** asked the Minister of Health the approximate cost per year of maintenance and treatment of the sick and infirm in the poor-law infirmaries.—Mr. **Greenwood** replied: The cost of poor-law relief in poor-law infirmaries for which separate accounts are kept, in the year ended March 31st, 1929 (the latest year for which particulars are available), was £5,379,000 approximately.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. C. Keating to be Surg. Lt.-Comdr.

Surg. Comdrs. W. Bradbury to R.M. Infirmary, Deal; H. E. R. Stephens to R.N. Hospital, Chatham; and W. P. Beattie to *Carlisle* and to *Cardiff*.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Lt. R. St. J. Lyburn to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

D. P. F. Mulvany is granted a temp. commn. in the rank of Lt.

TERRITORIAL ARMY.

Capt. J. Marshall to be Maj.

MILITIA.

Maj. D. Macfadyen retires on attaining the age-limit and retains the rank of Maj.

INDIAN MEDICAL SERVICE.

Capt. J. Carrey to be Maj.

Lt. L. G. Backhurst to be Capt. (prov.).

The provisional appts. of the undermentioned officers are confirmed: To be Capts.: J. McM. Wilder, E. G. Hunt Wood, R. L. Frost, K. S. Fitch, and W. T. Taylor. To be Lts.: E. P. N. M. Early, W. McAdam, J. H. Gorman, S. M. Kharegat, D. H. Waldron, E. B. Eedle, and A. B. Guild.

Capt. M. D. Minhas relinquishes his temp. commn.

Extension of Harrow Hospital.—The [illegible] ments now in progress, which will cost £50,000, will increase the number of beds from 40 to 75. Particular attention is being given to devices for making the bui[illegible] sound-proof.

MEDICAL NEWS

University of Oxford.

On Jan. 22nd the following degrees were conferred :—

D.M.—P. N. B. Odgers and P. L. Gibson.

B.M.—B. T. Squires, R. T. V. Clarke, W. G. Rees, Rosalind V. erguson.

Dr. W. D. W. Brooks has been elected to a Fereday Fellowship t St. John's College.

University of Cambridge.

On Jan. 23rd the following degrees were conferred :—

M.B. and B.Chir.—Hermon Taylor, R. H. Dyer, B. C. hompson, and F. H. Ward.

M.B.—A. J. Smyth.

B.Chir.—C. J. K. Hamilton and H. D. B. Kelly.

ociety of Apothecaries of London.

At recent examinations the following candidates were ccessful :—

Surgery.—G. C. Brown, University of Cambridge and St. Mary's osp.; W. G. Kingston, Middlesex Hosp.; S. H. Thaler, *y's* Hosp.; and M. R. Tuteur Samuel, Universities of eiburg and Manchester.

Medicine.—A. J. P. Coetzee, London Hosp.; D. R. Rigg, niv. of Sheffield; and R. Schauder, King's Coll. Hosp.

Forensic Medicine, Hygiene, and Insanity.—A. J. P. Coetzee C. L. Ferguson, London Hosp.; W. R. Packenham, V. of Oxford and St. *Mary's Hosp.*; and D. R. Rigg, v. of Sheffield.

idwifery.—G. C. Brown, *Univ.* of Cambridge and St. Mary's osp.; and A. E. Mathews and A. W. Toussaint, St. Mary's osp.

he Baths of Dax.

The authorities of Dax, the thermal resort in the Pau-arritz district, where mud baths are a conspicuous feature, ve a dinner on Monday last, Jan. 26th, at the Savoy otel to a group of medical men at which the increasing nenities of their spa were fully detailed. The Dax ganisation—the Société Immobilière et Fermière des ux Thermales et Minérales—was represented by its incipal officers, while among others who supported Sir Clair Thomson in the chair was the French Consul-General London and many well-known doctors. The prosperity the spa was proposed in a bi-lingual speech from the air, as Sir StClair Thomson was returning thanks for the ests to their French hosts; after which Dr. Leonard illiams gave a short discourse, with cinema illustrations, the climate and waters of Dax and their therapeutic dications. Dr. Williams referred to the many patients o would benefit by sojourn in a spot so beautiful, so airy, d yet so sheltered as Dax, quite apart from their availing emselves of the elaborate arrangements made for universal ulticing in the soft alluvial mud of the Adour. The tty address was followed by an informal debate in which any of the company, hosts, and guests joined. The rangements for the dinner were made by the Federation the Health Resorts of France, from whom all information ncerning hotel accommodation and railway travelling n be obtained through Mme. Juppé-Blaise, at Tavistock ouse (North), London, W.C.

yal Society of Medicine.

At a conversazione held at the house of the Society on ednesday evening, Jan. 21st, Dr. Arnold Chaplin spoke extempore piece, fully illustrated on the screen, in which threw pleasant lights on the characters of a group of storic persons, concerning whose failings the world has ade up its mind. Most of them were really great and arly all occupied in their day, for different reasons, a ghly important place in the eyes of their contemporaries. arting with Theodora, Justinian's famous empress, the turer begged indulgence for her crimes on the score of r supreme courage. For Catherine the Great he made an ology, perhaps of a cynical sort but none the less telling; excused her sexual vagaries on three grounds—namely, at her husband was a sot, that she pensioned off her vers liberally, and that she introduced contemporary, pecially French, literature into the Russian Court. The tength of Cromwell's character, and his astonishing titude as a general, displayed when a middle-aged amateur, re held by Dr. Chaplin to condone the Protector's faults; d Voltaire's genius, wit, and surpassing literary accomplishments were set out as more than compensating for any xity of morals according to strict standards. To Madame oland he accorded a moving tribute, and the Young etender he dismissed with contumely, adding a pictorial iticism of the "bonnie" Prince by showing his portrait middle age. Running comments upon the Marquise du âtelet, Voltaire's intimate, and the translator of Newton's incipia; upon William III., who defied the Catholic and l-powerful Louis XIV. as a leader in the Grand Alliance; and upon Georgina Duchess of Devonshire, who bought votes by her kisses from the electors of Westminster, completed a piquant address which closed with the question addressed to the audience—"Now, would you rather be weak and good or strong and bad?"

At the conclusion Sir StClair Thomson moved the thanks of the meeting to Dr. Chaplin for what he described as a "debunking" oration, the American adjective, as he explained, signifying the removal of bunk from a subject. Lord Dawson, deputising as President of the society for Dr. Watts Eden, said that the applause of the audience rendered it unnecessary to take a formal vote from the large attendance.

University of London.

University College.—Five lectures on The Modern Technique of Cytology are being given at the College by Prof. R. Chambers (New York), Dr. R. G. Canti, and Dr. R. J. Ludford, at 5 P.M. on Fridays, Jan. 30th and Feb. 6th, and Thursdays, Feb. 12th, 19th, and 26th.

University of Leeds.

Dr. A. St. G Huggett has been appointed to the newly instituted Readership in Pharmacology within the Department of Physiology.

University of Manchester.

Dr. H. S. Raper, F.R.S., Brackenbury professor of physiology, has been appointed a Pro-Vice-Chancellor.

Royal College of Physicians of Edinburgh.

The Morison lectures will be given at the College by Dr. D. K. Henderson at 5 P.M., on Feb. 9th, 11th, and 13th. His subject will be Social Psychiatry.

British Institute of Philosophical Studies.

Prof. J. S. Haldane, F.R.S., will preside at a meeting to be held at University College, Gower-street, W.C., at 8.15 P.M. on Tuesday, Feb. 3rd, when Sir J. Arthur Thomson will lecture on Purpose in Evolution.

Wellcome Museum of Medical Science.

This museum is being rebuilt and will remain closed until further notice.

Glasgow Students' Collection.

The sum of £15,000 was realised by the Students Charities' Day collection. This was £2300 less than the record total of last year. Since 1921 Glasgow students by these efforts have raised £119,630.

Harry Stewart Hutchison Prize.

The University of Glasgow announce that this prize, of the value of about £50, for the best writing or writings embodying original research work in a branch of medical science relating to children will be awarded this year. Medical graduates (of not more than ten years' standing) of all British, home and colonial universities may be competitors. Compositions must be submitted in proper form to the Clerk of the Senate before March 31st, 1931.

Fires in Hospitals.

On Wednesday last week a fire occurred in the machinery room attached to the X ray department of the new Margate General Hospital which was opened in July last. The whole X ray machinery equipment was destroyed and the basement completely burned out, but no injury was done to the building above. The replacement of the installation will cost from £1500 to £2000.—A few days earlier a fire broke out in the diphtheria ward of the White Hoe Infectious Diseases Hospital, near Douglas, Isle of Man. There were ten patients in the ward, and the hospital was nearly full, most of the patients being children. The fire was quickly extinguished and there was no personal injury.

Hospitals as Panel Chemists.

The Eccles and Patricroft Hospital was recently incorporated with the object of obtaining power, under the Health Insurance Act, to recover expenses incurred in providing drugs, food, and bandages for panel patients. This can only be accomplished by a hospital which has been appointed panel chemists, and an unincorporated hospital is not qualified for such an appointment. Acting on counsel's opinion, the Lancashire County Insurance Committee has now declined to accede to the hospital's request to be registered as a body entitled to receive such payments. The refusal is, however, understood to be based upon a technical flaw in the hospital's Articles of Association, and when the flaw has been rectified another application is to be made in the interests of the voluntary hospitals generally.

A Haig Maternity Home.

A maternity home as a memorial to the late Lord Haig has recently been opened by Lady Haig at Hawick, in Roxburghshire. The home, which has cost £2000, has been given by Mr. Norman W. Grieve, a native of the district.

A Broadcast Appeal.

On a recent Sunday Sir Ernest Wild, Recorder of London, broadcast an appeal on behalf of St. Peter's Hospital for Stone in Henrietta-street, Covent Garden. Within a few days the hospital received 6600 letters containing a total of £1445.

Donations and Bequests.

Among other bequests, the late Mr. Henry Lewis Doulton, of Putney Heath, and Ewhurst, Surrey, left £1500 to St. Thomas's Hospital; £1000 to the Royal Hospital for Incurables; £500 each to the Royal Hospital for Children and Women, Waterloo-road, and the Cancer Hospital, Brompton; and £100 to the Brompton Hospital for Consumption.—The trustees of the late Lady Cargill's estate have allocated £4000 to the Glasgow Royal Hospital for Sick Children, country branch; £3000 to the Glasgow Dental Hospital; £2000 to the East Park Home for Infirm Children; £1000 to the Glasgow Benevolent Society for the Relief of the Destitute Sick; £1000 to the Glasgow Royal Cancer Hospital; £500 to the Samaritan Society, Western Infirmary, Glasgow; and £500 to the Hospital for Sick Children, Glasgow.

Society of Apothecaries of London: Livery Dinner.

The Master of the Society of Apothecaries, Lt.-Col. C. T. Samman, presided on Tuesday last, Jan. 27th, over a Livery Dinner of the Society, the principal guests being the Lord Mayor of London, Sir William Phené Neal, and the Sheriffs. There was a large company present and the guests included many well-known persons.

After the loyal toasts the Master proposed the Lord Mayor and Sheriffs and the Corporation, adding that the toast did not require a syllable from him to commend it to the company. It was, he said, the first time for four years that the Lord Mayor had attended one of the Livery Dinners. The Lord Mayor, in his response, claimed for his office and for the government of the City of London a history of wise progress, so much so, that he, for his part, would hesitate to welcome any innovations without consulting the actions of his predecessors. Mr. Alderman and Sheriff Jenks, who also replied, confessed to not having realised previously the status of the Society as one of the qualifying medical bodies, an important position on which he offered his congratulations.

The presentation of the honorary diploma of the Society to Sir John Lynn Thomas, which followed, led to a description from the new licentiate of his professional career. Having declined the opportunity to succeed to his father's farm, and having, as he thought, a bent towards surgery, he served his time, in the old way, as an apprentice before starting to "walk the wards" of the London Hospital; and of his experiences at the outset he drew a vivid picture.

Prof. W. E. Dixon presented Mr. H. S. Wellcome, LL.D., to the Master as a recipient of the honorary freedom of the Society. He dwelt on Dr. Wellcome's patriotic actions at the outset of the war, when he placed the bureaux and laboratories of his firm at the disposal of the Government, organising also motor ambulances and flying hospitals. Dr. Wellcome was, said Prof. Dixon, a great medical and social benefactor. Dr. Wellcome, in reply, paid a tribute to the medical developments which marked the times, and which dated especially from the experiences gathered during the war. It was estimated, he said, that more lives were saved through the developments of medicine during the five years which followed the cessation of war, than had been lost during that struggle.

Dr. G. W. Cock then presented the Society with some pieces of early eighteenth century silver, in memory of the late Dr. George Wilks, a past master of the Society whose nieces, the Misses Lepard, were the donors.

The toast of the guests was proposed by Dr. Cecil Wall, Junior Warden of the Society, when Earl Russell replied.

INDEX TO "THE LANCET." VOL. II., 1930.

THE Index and Title-page to Vol. II., 1930, which was completed with the issue of Dec. 27th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Feb. 3rd.—5.30 P.M., ORTHOPÆDICS. (Cases at 4.30 P.M.) Cases will be shown.

WEDNESDAY.—5 P.M., HISTORY OF MEDICINE. Paper: Dr. Hubert J. Norman: Panel, Tuke, and Dacquin, and the Reform in the Treatment of the Insane. PSYCHIATRY: Members of this Section are cordially invited to attend. 8.30 P.M., SURGERY: PATHOLOGY. Special discussion on Indications for and the value of the Intravenous Use of Germicides. Openers: Mr. V. Zachary Cope and Mr. P. H. Mitchiner (Surgery); Dr. Alexander Fleming and Dr. T. H. C. Benians (Pathology). Other speakers will take part. THERAPEUTICS and MEDICINE: Members of these Sections are specially invited to attend and take part in the discussion.

THURSDAY.—8 P.M., TROPICAL DISEASES AND PARASITOLOGY: DISEASE IN CHILDREN. Special discussion on The Adaptation of European Women and Children to Tropical Climates. Openers: Dr. Aldo Castellani, K.C.M.G. (Hon.), and Dr. G. W. Bray (Tropical Diseases); Dr. A. R. Neligan and Dr. H. S. Sta (Disease in Children). Other speakers will take

FRIDAY.—10.30 A.M., OTOLOGY (Cases at 9.30 A.M.) Discussion: Tuberculosis of the Ear. Openers: Sir StClair Thomson and Mr. F. C. Ormerod. Cases and specimens will be shown by Mr. A. R. Tweedie, Mr. W. M. Mollison, Mr. H. A. Kisch, Mr. F. C. Ormerod, Sir James Dundas-Grant, and others. 4.30 P.M., LARYNGOLOGY (Cases at 3.30 P.M.). Members are asked to note the alteration in the time of this and future meetings. Discussion: Frontal Sinusitis and Its Treatment. Papers by Dr. J. S. Fraser and Dr. J. P. Stewart, Mr. Douglas Harmer and Mr. Bedford Russell, Mr. Walter Howarth. Illustrative cases and specimens will be shown by the above and by Mr. H. A. Kisch, Mr. V. E. Negus, Mr. Musgrave Woodman, and others. 8.30 P.M., ANÆSTHETICS. Paper: Mr. A. Dickson Wright: Spinal Analgesia, with Special Reference to Operations Above the Diaphragm.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY, West London Hospital, Hammersmith-road, W.

FRIDAY, Feb. 6th.—8.30 P.M, Discussion on Premature Senility, to be opened by Dr. H. H. Mills, followed by Dr. R. A. Young, Prof. F. G. Hobday, and Dr. Gordon Dewes.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.

WEDNESDAY, Feb. 4th.—3.25 P.M. (at the Alexandra Picture House, Camp-road, Leeds), Dr. Ronald Canti: Cinematograph Demonstration of Living Tissue Cells Growing in Vitro.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

MONDAY, Feb. 2nd.—8 P.M., Prof. L. C. Martin, D.Sc.: Some Modern Developments in Microscopy (3).

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Feb. 2nd.—5 P.M., Prof. H. H. Woollard: The Potency of the Pharyngeal Entoderm.

WEDNESDAY.—5 P.M., Mr. T. P. Dunhill: Malignant Disease of the Thyroid Gland—The Relation of its Incidence and Spread to its Embryology and Prognosis.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 2nd, to SATURDAY, Feb. 7th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Mon., 4 P.M., free lecture by Mr. Ernest Miles: Cancer of Colon and Rectum.—ST. MARK'S HOSPITAL, City-road, E.C. Thurs., 5 P.M., Free demonstration by Mr. E. T. C. Milligan: Diagnosis of Diseases of Rectum and Colon.—MAUDSLEY HOSPITAL, Denmark-hill, S.E. Fri., 2 P.M., free demonstration by Dr. J. Harris (Psychological Medicine).—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Fri., 4.30 P.M., lecture by Mr. Rodney Maingot: General Routine before Abdominal Operations. First of four lectures.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Special Course in Gynæcology. Mornings and afternoons.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham. Intensive Course. Second week. Further particulars from the Fellowship of Medicine.

KING'S COLLEGE, Strand, W.C.

MONDAY, Feb. 2nd.—5.30 P.M., Prof. J. Barcroft: Constancy of the Internal Environment (2).

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Feb. 5th.—9 P.M., Dr. Kinnier Wilson: Epilepsy: Its Variants and Their Treatment.

UNIVERSITY COLLEGE MEDICAL SCHOOL, University-street, W.C.

TUESDAY, Feb. 3rd.—5.15 P.M., Dr. W. Cramer: Filtrable Tumours.

CHARING CROSS HOSPITAL MEDICAL SCHOOL, Agar-street, W.C.

SUNDAY, Feb. 1st.—10.30 A.M., Mr. Eric A. Crook: Recent Advances in Surgery. 11.45 A.M., Dr. W. J. Adie: Early Diagnosis of Common Organic Nervous Diseases.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (Public Health Division), Keppel-street, Gower-street, W.C.

MONDAY, Feb. 2nd.—5 P.M., Mr. J. C. Dawes: Public Cleansing. Composition and Storage of House and Trade Refuse.

WEDNESDAY.—5 P.M., Dr. W. G. Savage: Food Poisoning.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 2nd.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Children's Diseases Clinics. Operations.

NATIONAL HOSPITAL, Queen-square.

MONDAY, Feb. 2nd.—12 noon, Dr. Greenfield: Neuropathology. Diseases of the Nerve Cell. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Symonds: Intracranial Complications of Otitis and Sinusitis.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Adie: The Treatment of Epilepsy.

WEDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Senile Tremor.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educative Exercises. (In Exercise Room.)

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Feb. 3rd.—5 P.M., Dr. S. E. Dore: Affections of the Hair and Hair Follicles.

THURSDAY.—5 P.M., Dr. A. M. H. Gray: Xanthoma. Herpes.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Feb. 6th.—4 P.M., Mr. H. Kisch: The Use of Radium in the Throat, Nose, and Ear.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Feb. 3rd.—3.15 P.M., Dr. C. C. Beatty: Lecture.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, Feb. 4th.—4 P.M., Mr. V. Z. Cope: Demonstration of Surgical Cases:

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.

THURSDAY, Feb. 5th—5 P.M., Mr. A. L. Walker: The Causes of Maternal Mortality.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.

WEDNESDAY, Feb. 4th.—4 P.M., Dr. Rickwood Lane: Laboratory Investigation of Glycosuria.

Appointments

BOWER, MARGARET I., M.B., Ch.B. Edin., has been appointed Asst. Medical Officer for the Outer Isles of Inverness-shire.

HARVEY, W. C., M.D., Ch.B. Glasg., D.P.H., Medical Officer of Health and Superintendent of the Isolation Hospital, Southgate.

HORTON, R. LISTER, M.S. Lond., F.R.C.S. Eng., Honorary Surgeon to the Dorset County Hospital.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.: CAMBROOK, J. D., L.R.C.P. Lond., M.R.C.S., L.D.S., Honorary Dental Surgeon; JAMES, G. W. B., M.D., B.S. Lond., Honorary Psychiatrist; LEWIS, D., M.R.C.S., L.R.C.P. Lond., and SUNDERLAND, A., L.R.C.P. Lond., M.R.C.S., Hon. Anæsthetists.

Vacancies

For further information refer to the advertisement columns.

Altrincham General Hospital.—Sen. and Jun. H.S.'s. At rate of £150 and £120 respectively.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.

Birmingham, City Babies Hospital, Canwell Hall.—Res. M.O. At rate of £100.

Birmingham, Erdington House Poor-law Institution, &c.—Res. M.O. £350.

Birmingham and Midland Eye Hospital.—Res. Surg. O. £110.

Birmingham City Education Committee.—Director of Child Guidance Clinic and Special Schools M.O. £600–£700.

Bolton, Townleys Hospital, Farnworth.—Asst. M.O. £225.

Bristol, City and County.—Asst. M.O. for Maternity and Child Welfare. £500.

Bristol City and County Mental Hospital.—Third Asst. M.O. £350.

Bristol Eye Hospital.—Res. H.S. £150.

Cancer Hospital, Fulham-road, S.W.—Physician.

Central London, Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Res. H.S. At rate of £75.

Charing Cross Hospital, W.C.—Asst. Obstetric Physician. Also Asst. Cas. O. and Res. House Anæsthetist. £100.

Chester Royal Infirmary.—H.S. to Ear, Nose, and Throat Dept. £150.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Derby, Derbyshire Royal Infirmary.—Two H.S.'s to Special Depts. Also Ophth. H.S. Each £150.

Dudley, Guest Hospital.—Asst. H.S. £160.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Surgeon to Nose, Throat, and Ear Dept.

Gloucestershire Royal Infirmary and Eye Institution.—2nd H.S. At rate of £120.

Great Yarmouth General Hospital.—Jun. H.S. £150.

Hospital for Sick Children, Great Ormond-street, W.C.—Refraction Asst. for Ophthalmic Dept. 1 gn. each attendance.

Inverness Royal Northern Infirmary.—H.S. At rate of £100.

Lincoln City.—Chief Asst. M.O.H. £600.

Madras Medical College and Vizagapatam Medical College.—Professorship of Anatomy. Rs.1100 a month.

Maidstone, Institution for Mental Defectives, Leybourne Grange.—Res. Med. Supt. £700.

Manchester, Ancoats Hospital.—Res. M.O. £150. H.P. £100. Res. Surg. O. £200. Also Gen. H.S. £100.

Minehead and West Somerset Hospital, Minehead.—Res. H.S. At rate of £150.

Nelson Hospital, Merton, S.W.—Res. M.O. At rate of £100.

Nottingham and Midland Eye Infirmary.—Res. H.S. £200.

Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.

Poole, Dorset, Cornelia and East Dorset Hospital.—H.S. At rate of £150.

Poplar Metropolitan Borough, Maternity and Child Welfare Clinics.—Part-time M.O. 1¼ gns. per session.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, Kensington, W.—Hon. Asst. Dental Surgeon.

Rochdale Infirmary and Dispensary.—Jun. H.S. £200.

Royal Northern Hospital, Holloway, N.—Asst. Surg. O. £75. Obstet. H.S. and H.S. Each at rate of £70. Also Hon. Surg.

St. Bartholomew's Hospital, E.C.—Surgeon.

Salisbury General Infirmary.—H.S. £150.

Sheffield, Royal Hospital.—Ophth. H.S. £120. Also Res. Anæsthetist. £80–£100.

Sheffield Royal Infirmary.—H.S. At rate of £80.

Southport General Infirmary.—Sen. H.S. £200.

South Shields, Ingham Infirmary.—H.S. £150.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. £150.

Swindon and North Wilts Victoria Hospital, Swindon.—M.O. £125.

Surrey County Council.—Asst. M.O. £600.

Uxbridge, Hillingdon Hospital.—Dispenser. £250.

Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of the Chest.—Asst. Res. M.O. At rate of £300.

Virginia Water, Surrey, Holloway Sanatorium.—Jun. Asst. M.O. £350.

Wallasey, Victoria Central Hospital.—Jun. H.S. At rate of £100.

West Bromwich and District General Hospital.—Hon. Physician and Hon. Surgeon. Also H.S., H.P., and Cas. H.S. All at rate of £200.

West Ham County Borough.—Jun. Asst. M.O. £500.

Wigan Royal Infirmary.—Third H.S. At rate of £150.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Dingwall (Ross and Cromarty), Rowfant (Sussex), Parbold (Lancs.), and at Margate (Kent).

Births, Marriages, and Deaths

BIRTHS.

POTTINGER.—On Dec. 15th, at Invercargill, New Zealand, the wife of David Pottinger, M.D. Ed., M.R.C.P. Lond., of a son.

SELBY.—On Jan. 24th, the wife of Dr. H. J. Selby, of Newnham-on-Severn, of a son.

TOWNEND.—On Jan. 20th, at Welbeck-street, the wife of R. D. M. Townend, M.R.C.S., L.R.C.P., of High-street, W., of a son.

TUNNICLIFFE.—On Jan. 22nd, the wife of S. L. Tunnicliffe, M.B., Ch.B., B.D.S., M.R.C.S., L.R.C.P., of Granby-street, Loughborough, Leicestershire, of a daughter.

MARRIAGES.

BATEMAN—TURNER.—On Jan. 15th, at St. Margaret's, Westminster, Geoffrey Hirst Bateman, B.M., B.Ch., to Margaret, only daughter of Samuel Turner, J.P., High Sheriff of Lancashire, and Mrs. Turner, of Bamford, nr. Rochdale.

DEATHS.

AMSDEN.—On Jan. 18th, at Seaview-terrace, Rye, Sussex, George Amsden, M.B. Edin., late Medical Superintendent Essex County Mental Hospital, in his 85th year.

CÆSAR.—On Jan. 16th, at Clapton-in-Gordano, Somerset, Richard Thompson Cæsar, M.C., M.R.C.S. Eng., L.R.C.P. Lond.

MARSHALL.—On Jan. 24th, at Beverley, Chorley New-road, Bolton, John Dodds Marshall, D.S.O., M.C., Ch.B.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

"WHAT TO DO IF IT'S CATCHING."

UNDER this catching title Messrs. Newton Chambers and Co., Ltd., have published, at the modest price of 1s., a compilation, to which, we are informed, medical and sanitary specialists have contributed, and which places in the hands of the public the elementary rules for the domestic dealing with infectious diseases. So far as this is possible or useful, having regard alike to the need for brevity and the nature of the audience, the authors have given correct reasons for the advice which they offer, thus showing that the scientific coöperation claimed has been real. The technical staff of the firm working under such advice have, in fact, produced a small and cheap book, consultation of which by the public should clear up much of the perplexities which exist in the lay mind concerning the origin, prevalence, and prevention of infectious disease; as a result of the lessons here given the general population should be able to assist intelligently in the promotion of health under the advice of the medical profession. There is nothing novel whatever in the teaching, but the selection and arrangement of the material should make learning easy.

After an appeal to commercial prudence by pointing out the expense incurred through the spread of sickness, the first section of the book indicates how the doctor, and, where necessary, the sanitary authority, can play their parts in the maintenance of public health. The prudent note is made here that the seriousness of many common and general illnesses should not be estimated by the immediate effects, which, as far as mortality statistics go, may not appear to be sinister, but by their after-effects, which bulk largely in many special directions. The part played by specific germs, and the consequent necessity of preventing their spread, is set out succinctly, and there follows a synopsis of the more obvious signs of common complaints in their earliest stages, which bears the mark of well-informed care. This section closes with the assumption that the medical man has been called in, when the sound suggestion is added that he should be asked—Can this illness spread to other members of the household, and, if so, is removal to a hospital or complete isolation necessary, or can a modified form of semi-isolation in the home be employed? The chapter in which the plan for "semi-isolation" is put out is very interesting. The familiar rules for sick-room arrangements and disinfection are fully laid down; they insure that the sufferer should be kept as far as possible from contact with the family and that, when such contact takes place, certain precautions to prevent the spread of infection should be observed. The stricter regulations to be followed by all members of the household when the patient is in complete isolation summarises advice that the doctor usually gives in such circumstances, but the clear and emphatic language employed should be helpful in ensuring an orderly and inclusive attention to the many things that have to be thought of. The verbal instructions of the medical attendant will be recalled, and therefore followed with the aid of this categorical list. A tabular statement as to the accepted periods of incubation of the main group of infectious diseases is then followed by indications of the period during which quarantine and isolation should be enforced, while wise recommendations as to the treatment of the patient, after the medical declaration that he is well enough to leave the sick room, are added.

Other sections of the book deal with first-aid in the home, lay down precepts of personal hygiene, and give household hints of various sorts to those responsible for the domestic care of the sick. Attractive little pictures break up the text throughout, and will certainly act as aids to memory.

WOUNDS AND MAGGOTS.

SUPPLEMENTING the leading article on this subject in THE LANCET of Dec. 13th, 1930 (p. 1301), Dr. Hyman I. Goldstein (New Jersey, U.S.A.) writes: Dr. W. S. Baer, of Johns Hopkins Medical School, addressed the Interstate Post-graduate Assembly of North America at Detroit (Oct. 25th, 1929) on the subject of "Viable Antiseptic in Chronic Osteomyelitis." Baer had seen two wounded soldiers in France get well as the result of maggots filling the wounds. He "mulled the problem over in his head for ten years." and he then decided to try out this maggot treatment in some cases of chronic osteomyelitis, not cured by several operations and various chemical "sterilising" agents. All of the 21 cases both of compound fractures and ordinary chronic osteomyelitis of most bones of the human body, got well under the maggot treatment. He believes maggots kill off gas-bacillus infection. But Baer evidently was unaware of the use of maggots by Baron Larrey during the Napoleonic wars, and makes no reference to Larrey's *Clinical Surgery*, nor to Malgaigne or Packard. Maggots were being used in Madrid in August, 1929, when I visited the hospital there with the Spanish resident surgeon. Baer, while stating that maggots will kill the gas bacillus, does not mention tetanus spores. Sterile maggots, however, are now being grown.

THE MYSTERY OF LIFE.

A FILM now being shown at the Rialto Theatre in Coventry-street, London, opens with some fantastic pictures showing our own solar system separating from stellar matter. The evolution of animal life is then traced from amœba to primitive man through different types of aquatic and terrestrial animals. The call of sex is introduced with examples of mating, of selection of the fit, and of the urge to carry on the race. Human ontogeny from the conjugation of ovum and spermatozoön up to the birth of the fœtus is set out in rapid sequence. Here one cannot help feeling that the story is insufficiently clear and full. The film, in fact, just loses the opportunity of being great. If, while retaining its directness and simplicity, it were revised so as to present the story in a more logical sequence, it might well prove to be one of the real educational agents of our time. Prof. Julian Huxley's name is mentioned as its instigator, and we could have wished that his help had been secured in the production.

ENGAGEMENTS IN ADVANCE.

FROM the Lecture Agency, Ltd., the Outer Temple, Strand, London, W.C., we have received a copy of the Advance Date Book, which will be found useful by all who have to make a note of their engagements some time before their performance. Bound in leather and conveniently small, the diary is ruled so that the entries for a month appear on one page, with the facing page left blank for remarks. In this way the period from July, 1931, to June, 1932, is covered, while there are preliminary spaces for brief entries up to June, 1931. The diary is accompanied by calendars dealing with the three years following June, 1931, while the feasts and anniversaries are indicated for four years. There is space at the end of the diary for memoranda and accounts, and the price of the book is 3*s*. 6*d*. post free.

ADDRESSES AND ORIGINAL ARTICLES

USES OF DIATHERMY IN MEDICINE AND SURGERY.*

By E. P. CUMBERBATCH, M.B. OXF., M.R.C.P. LOND., D.M.R.E.,

EDICAL OFFICER IN CHARGE OF ELECTRICAL DEPARTMENT AND LECTURER ON MEDICAL ELECTRICITY, ST. BARTHOLOMEW'S HOSPITAL.

TREATMENT by diathermy has been practised in is country for a little more than 20 years; it may said that it "came of age" last year. Its growth as slow *during its first decade. During* its second n years, however, it grew rapidly, and to-day there scarcely a region of the body to which it has not en applied.

The present occasion is opportune for reviewing e subject. The Medical Society of London includes ny of the London authorities in the various nches of medicine and surgery. Some of them ilise diathermy in their specialties, and it will be teresting to hear their experience and opinions on use in medicine and surgery. I much appreciate e honour of the invitation to open a discussion on e subject. Since diathermy is now employed in most all the specialties, it is manifestly impossible r any one worker to acquire practical experience every branch of medical and surgical diathermy. have, however, seen diathermy "grow up," as it ere, in the *hospital* where it was *first* employed in is country for medical and surgical purposes, and uch of the early work on diathermo-therapy was nducted there. In opening this discussion I believe will be the best plan to speak on the different ecialties in turn, relating my own experience d then asking you for yours, as well as your mments and criticism. A few introductory marks, however, on the properties and uses of athermy in medicine and surgery may not be out place.

Medical diathermy is given for the following purposes: to relieve pain and spasm, to raise temperature ich is pathologically subnormal, to lower blood essure which is unduly high, and to aid the resolution inflammation. It is also given intentionally for e purpose of aiding the tissues to free themselves om local and general infection. Recently in the ited States the entire body has been subjected to athermy for the purpose of obtaining a so-called herapeutic fever." In surgery diathermy is used the purpose of coagulating abnormal tissue en asse. It should be mentioned that a current pable of producing diathermy can also be used to ll tissue by desiccating it—i.e., by depriving it of ter. This form of surgical treatment, known as *siccation* or *fulguration*, is of high value in the eatment of morbid tissue which does not extend eply below the surface. The post-operative reaction scarcely noticeable, and the scars are the best tainable. This form of treatment is little known the general medical profession. I can recommend in particular to the dermatologist. A current pable of producing diathermy can also be made to vide tissue and excise it like a knife, and, at the me time, seal the divided capillaries and lymphatics. should be mentioned that these two last-mentioned forms of treatment, strictly speaking, are not diathermy.

Treatment of Special Regions.

I shall now take the various specialties in turn and speak on the uses of diathermy in each one.

GYNÆCOLOGY.

It is in the treatment of certain diseases peculiar to women that medical diathermy has achieved the most striking success. *By means of a suitable method* the urethra and cervix can be safely and painlessly heated to a temperature of 114° F. or nearly a degree higher. The object of heating them to this high temperature is to aid them in freeing themselves from infection. This treatment is given twice weekly during one or two intermenstrual periods. Its effect *is to remove all clinical signs of inflammation.* If the infection is gonococcal the organisms disappear. The *Streptococcus hæmolyticus* also disappears. Diphtheroid and coliform bacilli, and non-pyogenic streptococci and staphylococci, if present in the cervical secretion, sometimes persist after diathermy even though all signs of cervicitis disappear.

The results above-mentioned were obtained in 90 per cent. of gonococcal cases, and in 80 per cent. of non-gonococcal cases. The patients were followed up for two years, and the results were found to be permanent. The cases in which the treatment failed include those in which relapse occurred at later stages after apparent cure. Failure occurred in those cases where there was widespread infection of the pelvic supporting tissues.

The most effective method of subjecting the urethra and cervix to diathermy and obtain the high temperatures named is that devised by Dr. C. A. Robinson. He elaborated it during the ten years when he was investigating the effects of diathermy in pelvic diseases in the electrical department of St. Bartholomew's Hospital. He found that it was necessary to introduce an active electrode into the channel of the urethra *or canal of the cervix.* Simpler methods, in which an electrode is placed in apposition with the cervix, were found to be unsatisfactory. Time does not allow a description of Dr. Robinson's technique. His method of heating the urethra and cervix to a temperature of 114° to 115° F. is very ingenious. It needs skill and practice in intrapelvic manipulation, but it is the *most efficient* method that has yet been devised.

I might digress here for a moment and say that temperature as high as those mentioned can only be obtained in regions which are close to the electrodes. I mention this fact because it is sometimes stated that *any degree* of heat can be obtained in *any part* of the body by means of diathermy. Down in the depths *of highly* vascular regions such as the thorax and abdomen I believe it impossible to procure more than a very slight rise of temperature—that is, when the electrodes are placed in contact with the skin. In the pelvis, however, one of the electrodes can be placed in close proximity to some of its organs, and these can be subjected to the maximum, or nearly the maximum, permissible degrees of diathermy.

The tubes and ovaries can be subjected to diathermy by using a special vaginal electrode. By reason of their deeper situation it is not possible to heat these parts to the same high temperature as the urethra or cervix. The relatively minor degree of therapeutic pyrexia that can be produced in the tubes is very often successful in bringing *salpingitis* to an end, both in gonococcal and non-gonococcal cases. In Dr. Robinson's experience the proportion of successful results reached 80 per cent. If pus is present in the tubes, however, surgical operation is necessary. If the pus is gonococcal it tends to become sterile of its own accord. Diathermy may then be applied to the infected cervix and afterwards to the tubes. In some cases this treatment seems to aid absorption of the sterile pus.

---

* Opening a discussion at the Medical Society of London on n. 26th.

General pelvic diathermy is very successful in *dysmenorrhœa*, due to a minor degree of salpingitis. On the other hand, the treatment has no permanent effect in cases of dysmenorrhœa of the spasmodic type. Patients say they are much better during the period after the first course of diathermy, but if further courses are given they say that their improvement is not maintained. Ultimately they return to their original condition.

General pelvic diathermy seems to influence the endocrine functions of the ovaries. If cessation of menstruation is premature, this treatment will frequently cause its return even though it may have been absent for two, three, or even more years. In one case it returned after ten years' absence. Another fact which seems to indicate the influence of diathermy on the endocrine functions of the ovaries is the cessation of climacteric bleeding during the treatment and the alleviation of the symptoms which sometimes occur prior to the change of life.

The statements I have made on the effects of diathermy in diseases of women are based on the results obtained by Dr. Robinson during the ten years when he worked in my department in St. Bartholomew's Hospital. He has conducted similar work for a still longer time at the West Middlesex Hospital. He has acquired an enormous and unique experience; and I hope that he may be persuaded to publish it before long.

Before concluding my observations on diathermy in gynæcology I should like to call to your attention the work of Dr. Robinson in the treatment of *puerperal fever* by the same agent. By means of intrapelvic diathermy he succeeded in curing 33 out of 39 cases. This work is entirely original. As far as I am aware no other method has been so successful. The usual prophylactic precautions were taken, and diathermy was not applied in any of the cases before the fever had been in existence for seven days. Dr. Robinson has communicated his results to the Hunterian Society and to the Section of Electrotherapeutics of the Royal Society of Medicine.

DISEASES PECULIAR TO MEN.

I believe there are some specialists in men's diseases who utilise diathermy in the treatment of certain maladies of the prostate, epididymis, &c. I should like to hear the results they obtain. My own experience extending over 12 years, and derived mainly from cases which had resisted treatment elsewhere, leads me to conclude that results nearly as consistent as those obtained in infection of the uterus and its adnexa can be procured in certain infective diseases of the organs peculiar to men. The most successful results are found in cases of gonococcal infection. The best of all are obtained in gonococcal infection of the epididymis and other scrotal contents. The rapid alleviation of the pain and the subsidence of the swelling and disappearance of the tenderness can be regarded, I think, as one of the most constant phenomena of therapeutics.

Most of the cases of *gonococcal prostatitis* and *vesiculitis* which I have had under my care or observation have responded satisfactorily to diathermy. The treatment was applied by way of a rectal electrode. Cases in which the gonococci could not be made to disappear from the secretion under other forms of treatment were no longer found after diathermy. Some of these were afterwards subjected to a marriage test, and they passed it satisfactorily. The greatest difficulty is experienced in cases giving a history of gonorrhœa a long time ago and a persistent morning gleet. Gonococci have been searched for from time to time but never found. I have treated a number of cases of this kind by diathermy. In a few the pus cells disappeared and the gleet was not obser after the cessation of the treatment. More oft however, the pus cells could not be made to disappear, and the gleet persisted. Consequently no final conclusion can be made in regard to the absence presence of gonococci in the tissues before or diathermy.

In regard to *anterior urethritis* the action diathermy is disappointing. It does not bring the rapid abortion of the infection that occurs urethritis in the female is treated by the same I have treated a few cases by diathermy, but discharge came to an end no sooner than might been expected if other methods had been em In the methods which I used for subjecting the m urethra to diathermy, there was no passage instruments into the urethra. One of the elect was placed in apposition with the prostate, the oth with the penis. It is just possible that the inclusion the prostate in the diathermy may prevent metasta infection.

In the discussion on the uses of diathermy in disea of the prostate I should like to hear the experien of the surgeons who have employed the operatio introduced by Luys for punching out that part of th middle lobe when it obstructs the urethra. My ow experience of diathermy in senile enlargement of th prostate is mainly restricted to that of a few cas in old men who were unfit for surgical operatio I treated them by *medical* diathermy, but it is doubtf whether they derived any benefit. Quite recently however, I have had three cases in men aged 60, 6 and 60 respectively. In these cases the sympto of obstruction were not of long duration. The patie complained of difficulty in emptying the bladder rising in the morning, and of the necessity of getting up at night to micturate. Diathermy removed the symptoms. One patient has been free for th months, another for the same length of time, and th third for 16 weeks. It is possible that the obstructio in these cases was due to congestion of the enlarg prostate. Diathermy would be expected to remove

DISEASES OF JOINTS.

It is probable that most of those who are pres have been troubled with difficult cases of arthri Those who practise the physical branches of medic are troubled with them all the time. If the ca sent to the electrical department of a hospital we classified numerically it would probably be fo that arthritis headed the list. If they were classi in accordance with the degree of benefit derived fr electrical treatment it would have been found, bef the days of diathermy, that arthritis came near th bottom of the list. Since the advent of diatherm however, it has obtained a better position. Near th top of the list would be placed gonococcal ar In the treatment of this type of joint disease it imperative that the prostate and vesicles (in me and the cervix uteri (in women) should be sub to the diathermy. It is not necessary to apply it the joints themselves. This form of treatment bri he arthritis to an end, and it does so—in my experience—invariably. If the cases are early it can truthfully be said that cures are obtained. In late cases, in which permanent structural changes have occurred in the joints, the arthritis is arrested. The fire is extinguished, and it remains to effect such repair of the joints that can be brought about by means of physical treatment. If non-gonococcal infective arthritis in women is investigated, it will frequently be found that cervicitis exists, even though there may be no outward or visible evidence of it, and no notice of it on the part of the patient. In cases of this kind the application of diathermy to the cervix will bring the arthritis *to an end in about 75 per* cent. of the cases.

It is probable that infection of the *prostate* by organisms other than the gonococcus can give rise arthritis in men. I have had cases which presented bacteriological evidence of gonococcal infection and gave no history of it. In some of these the treatment of the prostate and vesicles by diathermy brought the arthritis to an end. It is possible that ro of the cases would have responded to the tment if the diathermy had been administered the *urethral* instead of the *rectal* route. The cles can be heated to the highest temperature by rectal route, but in order to heat the whole state to the same degree an active electrode uld be introduced into the posterior urethra. A ecial electrode has been devised for this purpose Dr. G. F. Stebbing. I have not yet used it, but e treatment of the prostate by the urethral route is well worth investigation.

There is another variety of arthritis in women hich responds well to pelvic diathermy. I refer the type which is recognised by some workers and med *menopausal arthritis*. It occurs just after, a little before, the cessation of menstrual life. The menopause may, in fact, be premature. The patients y that they have increased in weight or become outer. On examination it is found that there are ds of tissue resembling fat just above the knees d in the upper arms. It is in the knees that pain often felt. In these joints the synovial membrane thickened. The treatment of this type of arthritis pelvic diathermy relieves the pain and causes e disappearance of the pads above-mentioned. If e cessation of menstruation is premature the return the periods is often observed by the patient. These ts have led my co-worker, Dr. Robinson, to formue the theory that this type of arthritis is due disturbance of the endocrine function of the *ovaries*. has an interesting collection of cases of this kind the London Clinic.

It is too soon to speak about permanence of results, t if the cases are treated before permanent organic anges have taken place in the joints, it is possible at real cures may be obtained. Two private patients rsonally known to me had the treatment in the rly stages of their complaint. One was treated months ago, and the other four years ago. Both w are perfectly well.

Before leaving the subject of arthritis I would like present the following hypothesis as a "bait" to ose present in case any member might "rise to it." suggest that there is a "climacteric" arthritis ich may occur in men at the time of life when anges occur in the prostate. Men are prone to velop arthritis between the ages of 50 and 60, and know of cases in patients at this time of life which ve derived considerable relief after prostatic athermy. Apart from clinical results, however, is is a matter for speculation, and he who possesses the largest amount of clinical and pathological knowledge and the greatest agility in argument will outrun his opponent in the discussion.

DISEASES OF THE CIRCULATORY SYSTEM.

There are some diseases of the circulatory system for which diathermo-therapy is recommended by certain authorities. The late Sir Clifford Allbutt was a strong advocate of the use of high-frequency currents for *hyperpiesia*. In an article on the subject by him in the "Index of Treatment" (8th ed.) he mentioned that Lewis Jones had likewise obtained good results and attributed them to diathermy. Speaking from my own experience, I should say that the few cases which have been referred to me derived further benefit from general diathermy after general medical treatment had been instituted. Pain in the chest, dyspnœa, and headache were relieved. In regard to its effect on the *blood pressure* general diathermy, in my experience, reduces both the systolic and diastolic values, but if they are not very high at the commencement of the treatment (say in the vicinity of 200 mm. systolic and 100 mm. diastolic) they return in a day or two to their original values. But if they are much higher at the beginning of treatment the reduction is more sustained. It lasts, at any rate, during the period of the course of treatment. In regard to subsequent values as time goes on I cannot say much. Two patients have been under my care for a number of years. They obtain relief from diathermy, go away, and return after 6 to 12 months saying that their symptoms have returned. I find that the blood pressure is sometimes at its original value, sometimes a little lower. Relief is again obtained from diathermy, and they go away for another period until their symptoms return.

In the treatment of *angina pectoris* diathermy has been recommended by Prof. John Hay. It was originally advocated for this disease by Nagelschmidt, the German protagonist of diathermy. Dr. John Dyson has procured freedom from attacks for periods as long as two years. Some of his cases, I believe, were sent to him by Prof. Hay. I have had no experience of cases in which there were sudden attacks of violent pain. Other cases in which the patients complained *of pain in the chest* only during exertion ("angina without agony") have been referred to me for diathermy. Three out of five cases said they felt no better after the treatment. In the fourth case the patient had no pain for at least six months after a course of diathermy. The fifth patient said she did not feel much better directly *after the diathermy*. But soon after her return to her home in the country she wrote to say that she had lost all her symptoms and was able to walk up hills without feeling pain or shortness of breath.

In regard to *intermittent claudication*, I am rather disappointed with the results of diathermy. Some of my cases appeared to have been quite distinctly benefited by diathermy. These cases were in very active and hard-working men, but rest had been prescribed for them by the good physician. In two cases the prescribed rest could not be obtained, and no benefit was derived from diathermy. The limping persisted. In one of the cases, however, there was a complaint of pain in the foot which kept the patient awake at night. This symptom disappeared.

DISEASES OF THE LUNGS.

The treatment of *lobar pneumonia* by diathermy has caused much comment. Several hundred cases have been treated by its means in the United States by Eaton Stewart. Much has been said for and against this form of treatment. It has been tried by Dr. Morley Fletcher in this country in 12 cases. It was found to relieve pain and procure sleep. The patients preferred it to poultices and antiphlogistine. In the West Middlesex Hospital 200 cases have been treated under the direction of Dr. Robinson. Diathermy has been adopted there as the standard treatment, and a small ward has been equipped for the purpose. It is much too soon to say anything final in regard to the effect of diathermy on the mortality-rate.

Pulmonary diathermy has also been recommended for the so-called *idiopathic asthma.* My own experience is limited to two cases which had resisted other forms of treatment. The patients liked the treatment, and said that their attacks were less severe and frequent during the course of diathermy.

DISEASES OF THE ALIMENTARY CANAL.

There is not much to say on the effects of diathermy in diseases of the alimentary tract. In *mucous colitis,* however, I have found pelvic diathermy of high value. The cases I have treated have been in young women. The treatment administered twice weekly for three or four weeks caused the disappearance of the mucus and a reduction of the frequency of defæcation until properly formed stools were passed once a day. Some of the patients relapsed, but repetition of the treatment had the same effect. Dr. Claughton Douglass has treated some cases by the same method and has had good results.

In painful *fissure of the anus* I usually find that rectal diathermy gives prompt relief. Pain due to internal hæmorrhoids has always been relieved by the same treatment in the few cases which I have had under my care. There are some workers in this country who employ surgical diathermy for the treatment of hæmorrhoids. Others destroy them by fulguration (desiccation).

DISEASES OF THE SKIN.

Certain abnormalities of the skin can be well treated by surgical diathermy or fulguration. Smooth non-contracting scars are left after the former. After fulguration, as I have already said, the reaction is scarcely noticeable and the scars are perfect. Papillomata of the skin can be soon dried up, by fulguration, into small hard masses which can then be picked off. The same method is rapid and effective for the so-called "mulberry nævus," for capillary nævus, for telangiectasis, for flat and pedunculated warts, and for pigmented areas of skin. For epithelioma of the skin surgical diathermy is a most useful form of treatment. I have had at least one case where it succeeded after radium had failed. Diathermic coagulation and fulguration are both of value in cases of *lupus vulgaris.* Of the two I prefer the latter, because the scab following the treatment acts as a protective dressing and covers the treated part until healing is complete, whereas after diathermic coagulation the slough has to separate, leaving, for a time, an open wound. In the treatment of lupus vulgaris by these electrothermic methods the chief difficulty is experienced in cases presenting scarred areas with persistent nodules after other forms of treatment have been tried. I have kept one case under observation and occasional treatment for 15 years. It was sent to me after a course of X ray treatment. Fulguration caused the nodules to disappear. But as time elapsed minute areas of recurrence were observed. Further fulguration was always successful, and it is interesting to note that the scars maintained their good character, despite the repetition of the treatment. One area, not treated by X rays, showed no recurrence after the first fulguration which was given ten years ago, and the scar remains as good as ever.

DISEASES OF THE EYE.
